Simulating AMOC tipping driven by internal climate variability with a rare event algorithm

Matteo Cini [1,2✉], Giuseppe Zappa[2], Francesco Ragone[3,4] and Susanna Corti[2]

This study investigates the possibility of Atlantic Meridional Overturning Circulation (AMOC) noise-induced tipping solely driven by internal climate variability without applying external forcing that alter the radiative forcing or the North Atlantic freshwater budget. We address this hypothesis by applying a rare event algorithm to ensemble simulations of present-day climate with an intermediate complexity climate model. The algorithm successfully identifies trajectories leading to abrupt AMOC slowdowns, which are unprecedented in a 2000-year control run. Part of these AMOC weakened states lead to collapsed state without evidence of AMOC recovery on multi-centennial time scales. The temperature and Northern Hemisphere jet stream responses to these internally-induced AMOC slowdowns show strong similarities with those found in externally forced AMOC slowdowns in state-of-the-art climate models. The AMOC slowdown seems to be initially driven by Ekman transport due to westerly wind stress anomalies in the North Atlantic and subsequently sustained by a complete collapse of the oceanic convection in the Labrador Sea. These results demonstrate that transitions to a collapsed AMOC state purely due to internal variability in a model simulation of present-day climate are rare but theoretically possible. Additionally, these results show that rare event algorithms are a tool of valuable and general interest to study tipping points since they introduce the possibility of collecting a large number of tipping events that cannot be sampled using traditional approaches. This opens the possibility of identifying the mechanisms driving tipping events in complex systems in which little a-priori knowledge is available.

INTRODUCTION

The Atlantic Meridional Overturning Circulation (AMOC) is a large system of ocean currents within the Atlantic Ocean of key importance for climate since it regulates the meridional transport of heat and freshwater[1,2]. The major supplier of the AMOC lower limb is the sinking of cold and salty dense water in the subpolar North Atlantic[2], mainly as a result of intense turbulent heat loss to the atmosphere in winter.

The AMOC is projected to weaken in response to anthropogenic climate change, due to a decrease in the surface density of the sea water in the subpolar North Atlantic[3,4]. Numerical experiments have shown that AMOC weakening can induce widespread regional and global climate impacts, such as significant decreases of Northern Hemisphere surface temperature, increases of Arctic sea ice and changes in the atmospheric circulation affecting global precipitation patterns[1,5–7]. In particular, in response to an AMOC weakening, the InterTropical Convergence Zone (ITCZ) tends to shift southward, while the Northern Hemisphere mid-latitude jet moves on average northward[1,5].

Of particular concern is the possibility that the AMOC, a key tipping element of the climate system, may pass a tipping point and reach a collapsed or substantially weakened stable state[2,8–13], which the sixth assessment report of the IPCC summarises as a low probability event but with a potentially very high impact on climate[3]. AMOC multistability is related to the salt-advection feedback, i.e., the fact that the AMOC transports salty surface water to the North Atlantic. The stronger the AMOC, the saltier the surface North Atlantic Ocean, thus promoting a more sustained deep convection which in turn reinforces the AMOC itself, and vice versa. Several studies have established that rapid changes in the

AMOC triggered abrupt climate transitions between glacial and interglacial phases in the Pleistocene, such as Dansgaard-Oeschger (DO) events[2,14–20].

The studies on the weakening and/or stability of the AMOC are usually performed in simulations with external forcing elements like greenhouse gases[1], freshwater[5–7,21] or surface heat[22] perturbations. This allows the analysis of the climatic response to an AMOC slowdown and assess if the system has passed a bifurcation tipping point, so that it would remain in the new collapsed state following a relaxation of the forcing elements[2]. The passing of a tipping point may also depend on the time scale of the forcing element, i.e., the critical threshold depends on the rate of change in the forcing[23–25].

However, understanding the possibility of a noise-induced tipping of the AMOC is equally important. By noise-induced it is meant a spontaneous transition of a system between two distinct stable states via its own internal chaotic variability without any external forcing[3]. First of all, within long, paleo-climatic time scales, even rare events with very long return times have a non-negligible probability to occur. Dramatic spontaneous AMOC slowdowns appear in multi millennial simulations[14,26–29], which are relevant for the study of past climate transitions, e.g., DO events. Secondly, even in forced experiments an AMOC collapse is generally achieved through the combined action of external forcing and internal variability, so that the passing of the tipping point may be anticipated or delayed because of internal climate variability. Lastly, in simulations with forcing elements it may be difficult to isolate the impacts derived by the AMOC slowdown from the impacts derived directly by the forcing itself.

The red lines represent the AMOC ensemble-mean evolution for each simulation. The blue points represent the values of the AMOC in all the 100 ensemble members of each simulation. The horizontal grey lines indicate the mean (full), plus/ minus 2-standard-deviations (dashed), AMOC variability in the control run (**a** in grey).

The uncertainty in the AMOC projections could be attributed either to differences in model formulations[1] or to the role of internal variability[30]. A recent study showed that at least in one state-of-the art climate model, projections under the SSP2-4.5 scenario may either evolve into an AMOC collapse or recovery solely because of internal variability[31,32]. We need, consequently, to assess the potential of internal climate variability in triggering a noise-induced tipping of the AMOC.

To sample a spontaneous AMOC tipping event, very long ensemble simulations would be needed. This can become computationally untenable in particular when one wants to sample a large number of events to study the mechanism involved in the collapse on a robust physical basis. To tackle this problem, here we propose the application of a rare event algorithm in order to internally guide the coupled atmosphere-ocean system towards rare trajectories associated with a decline of the AMOC. A different rare event algorithm has been recently applied to study ocean circulation noise-induced temporary transitions in a oceanic box model[33].

Rare events algorithms are computational techniques developed in statistical physics applied to a wide range of subjects (e.g., matter physics, chemistry, biology)[34,35] whose aim is to reduce the computational effort necessary to sample rare events in numerical simulations. The rare event algorithm used in this work has been previously applied to the computation of extreme heat waves in Europe[34–36], while other rare event algorithms have been applied to study midlatitude precipitation[37] and tropical storms[38,39]. The rare event algorithm here applied consists of a set of killing and cloning rules applied along the evolution of an ensemble simulation in order to populate the ensemble with model trajectories that feature rare values of a target metric of interest. In our case the metric is the value of the AMOC index between 46–66°N, which the algorithm seeks to reduce, by cloning the members with a weaker AMOC, and killing those with a stronger AMOC (see methods and Supplementary Fig. 1). The rare event algorithm is applied to an intermediate complexity coupled climate model, composed by the Planet Simulator (PlaSim)[40,41] and the Large Scale Geostrophic Ocean (LSG)[42,43]. The current version of this general circulation model has been recently applied to similar studies[44–46], including AMOC variability[45], and in particular has been recently applied with the rare event algorithm to study Arctic sea ice extreme melting events[46]. All simulations

are performed at stationary greenhouse gases forcing. In this setup, by construction, any tipping is necessarily induced by the internal climate dynamics.

Overall, the goal of the paper is condensed in two main research questions:

- Is a rare event algorithm able to sample spontaneous AMOC collapses driven by the internal variability of the coupled climate system?
- What is the climate response to a spontaneous AMOC collapse as well as the initial physical processes triggering the AMOC spontaneous collapse?

RESULTS
AMOC spontaneous slowdowns
The PlaSim-LSG control run (Fig. 1a, grey line), performed as a single member simulation over 2000 years[44], shows a realistic natural variability of the AMOC ranging between 17–21 Sv with oscillations taking place over different time scales. The AMOC variability appears to be stable over the 2000 years of the simulation. However, a different behaviour quickly emerges as the rare event algorithm is switched on. A rare-event 100-member ensemble simulation initialised at the end of the control run (red line in Fig. 1a) shows a dramatic decrease of the AMOC, which reaches values clearly outside of the previous boundaries. The system is now exploring states with a significantly weakened AMOC. The weakening is also reached in a short time scale, and with a rate of change substantially exceeding that of the fluctuations characterising the control run. It is worth to stress that this is obtained without applying any external forcing. The algorithm samples rare trajectories where the AMOC weakens purely due to internal variability via atmosphere-ocean-ice interactions.

To test the robustness of this behaviour, we compare the results from 10 independent rare-event simulations in Fig. 1b. All the simulations follow the same qualitative time evolution: an initial slow weakening of the AMOC followed by an abrupt transition resembling the passing of a tipping point that leads to a final plateau-like weakened AMOC state. The simulations differ in the timing of the abrupt collapse and in the final value of the AMOC, which ranges between 7.7–11.4 Sv. An equivalent time evolution is

also obtained when the AMOC maximum is evaluated within the entire North Atlantic Ocean, rather than in the 46–66° N band (see Supplementary Fig. 2). The main difference is that the basin wide AMOC maximum remains slightly higher (around 14 Sv), implying that the AMOC remains active in the subtropics. This difference is consistent with the fact that the algorithm seeks to minimise the AMOC at 46–66° N.

Climate responses to the AMOC slowdown
By years 115–125, the abrupt weakening of the AMOC is associated with widespread changes in a number of key oceanic and atmospheric climate aspects. We examine these responses in terms of anomalies compared to the control run (Fig. 2).

The response in the meridional overturning stream function (Fig. 2a) reveals that even if the changes peak around 50°N, the anomaly is widely spread throughout the Atlantic. Consistently with these circulation changes, anomalies in the oceanic convection frequency show the extinction of the branch of deep water formation over the Labrador Sea (ratio anomalies/climatology is almost -1 everywhere) in favour of a relative intensification of deep water formation in the Norwegian Sea (Fig. 2b).

The slowdown of the AMOC induces a general decrease of temperature in the Northern Hemisphere, especially in the Labrador Sea and Baffin Bay areas, which is consistent with the collapse of oceanic convection and a reduced meridional oceanic heat transport (Fig. 2c, d). The intense signal over the Labrador Sea (up to −11°K anomaly) is also associated with sea ice growth (Supplementary Fig. 3). In contrast, there are warming areas over the Weddel Sea and in the Greenland-Iceland-Norwegian (GIN) seas. The GIN seas warming is associated with a spot of increasing convection (Fig. 2b). Indeed, in that region, in our model, convection brings to the surface warmer waters, since oceanic levels below the uppermost have a higher potential temperature. Another study on spontaneous cooling events associated with a general decrease of the AMOC, documented a similar increased oceanic convection over Norwegian Sea[29]. Overall, the abrupt

AMOC weakening (up to 50% even considering the whole North Atlantic) results in a surface temperature drop of the order of 1.5°K over Northern Hemisphere continents, and of 0.5°K in the global mean.

The altered meridional temperature gradients induce changes in the mid-latitude jet streams (Fig. 2e, f). The dominant effect is a strengthening and poleward shift of the Northern Hemisphere jet stream in the zonal-mean. However, changes in zonal wind at 850 hPa show different responses in the individual ocean basins. A predominant poleward shift characterises the North Atlantic jet, while the North Pacific jet tends to strengthen and slightly shift southward. This pattern is found even at higher altitude (300 hPa, not shown) suggesting that the contribution to the strengthening of the zonal-mean jet comes from the North Pacific region, while the contribution to the poleward shift comes from the North Atlantic region. These signals are relatively strong, regionally up to 25% of the climatological amplitude at 850 hPa.

Precipitation anomalies, despite the coarse resolution of the model, are broadly consistent with the well-known southward shift of the ITCZ and the North Atlantic decrease of precipitation associated with AMOC slowdowns[1,5–7]. Indeed, in response to the AMOC decline, precipitation reduces in the Northern part of the Tropics (Supplementary Fig. 4a), weakening the climatological maximum, while it increases in the Southern Tropics. Supplmentary Fig. 4b further shows a decrease in precipitation in the North Atlantic exceeding 300 mm of yearly accumulated rainfall. The southward shift of the tropical precipitation has been linked to the southward migration of the annual mean Northern Hadley cell[6], while the decrease of precipitation in the North Atlantic has been attributed to reduced evaporation from the cooler ocean and to a reduced atmospheric eddy moisture transport[1,5]. Other regional tropical precipitation changes should instead be interpreted with caution given the reduced complexity of the model.

In general, for what concerns the climate response to the AMOC slowdown, there is a very good agreement of our simulations with other studies on AMOC slowdown under anthropogenic forcing[1,2,5,7,29]. This study shows large-scale patterns for near surface temperature and zonal wind anomalies similar to state-of-the-art climate models with external forcing elements. This clearly suggests that the main mechanisms of the climate response to the AMOC weakening are already contained in this simplified setup composed by an intermediate complexity model and performed with internal-variability driven dynamics only.

Role of internal variability for AMOC slowdowns

In order to identify the aspects of the internal climate variability that favour the AMOC slowdowns we examine the difference in the annual-mean climate between the ensemble members that are replicated versus the full set of ensemble members. This approach enables to highlight the climate aspects that, in a 1-year timescale, are statistically associated with a larger weakening of the AMOC and then are the most likely to be cloned by the algorithm. In this time scale, most of the ocean variability is expected to arise via atmosphere-ocean interactions (see Triggering Mechanisms in Methods), such as resulting from surface exchanges of heat, fresh water and momentum as discussed in Gregory et al.[22]. Atmospheric internal variability, which has large control on surface fluxes, is indeed a well-known driver of interannual and multidecadal AMOC variability[11,45,47–50], but its role in triggering abrupt changes or collapses of the AMOC is much less understood and atmosphere-ocean interactions that may prevent or favour the AMOC collapse have both been suggested[2,11,15,26].

We find that the ensemble members that develop a weaker AMOC are on average characterised by stronger North Atlantic westerly winds in the core of the jet, increased net freshening of the northern North Atlantic, and a more complex pattern of turbulent heat flux anomalies (Fig. 3). However, the wind stress

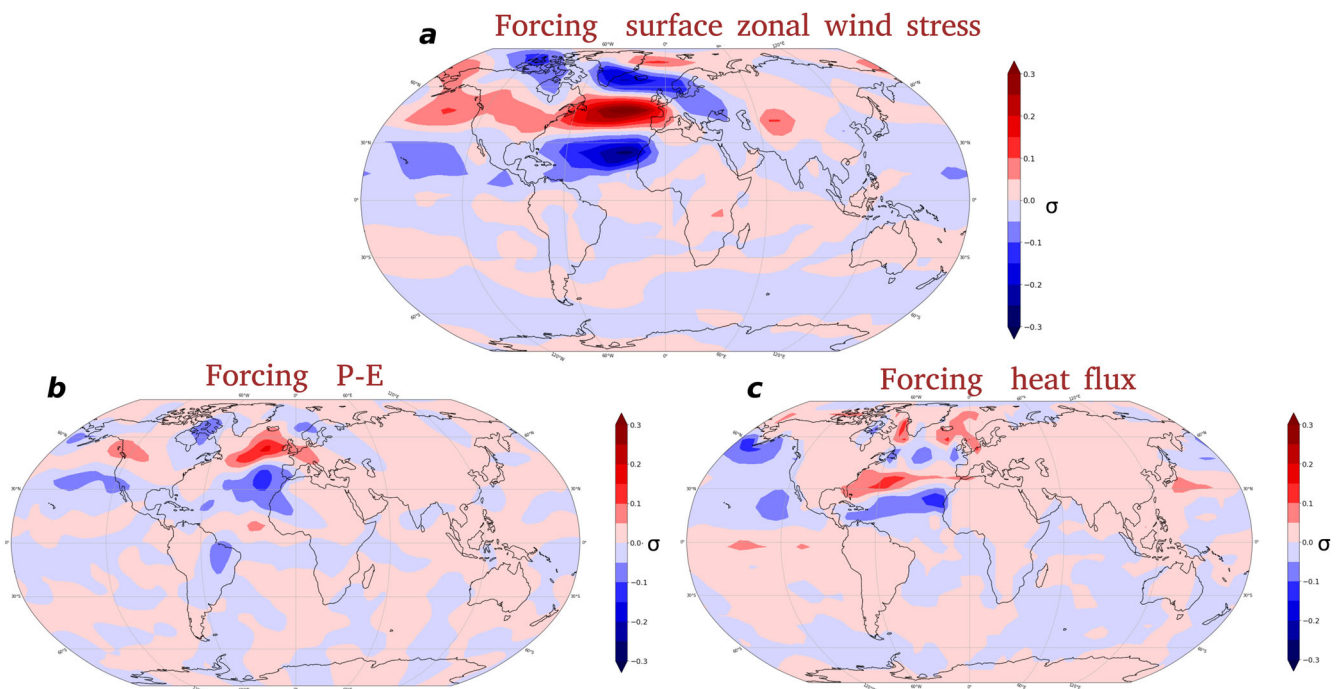

Fig. 3 Role of internal variability for AMOC slowdowns. Possible aspects of internal climate variability driving the AMOC slowdown in the rare-event-algorithm simulations. This is obtained as the difference between the annual-mean climate of the cloned members relative to the annual-mean climate of all members (see methods). The panels show the anomalies in (**a**) the zonal surface wind stress, (**b**) the freshwater flux (difference between precipitation and evaporation) and (**c**) the net heat flux (turbulent, sensible and radiative) between the atmosphere and the ocean. Positive values reflect anomalies toward the ocean. All values are expressed in terms of sigma units, where sigma represents the amplitude of the inter-annual variability, as given by the averaged standard-deviation across all ensemble members for each resampling time step.
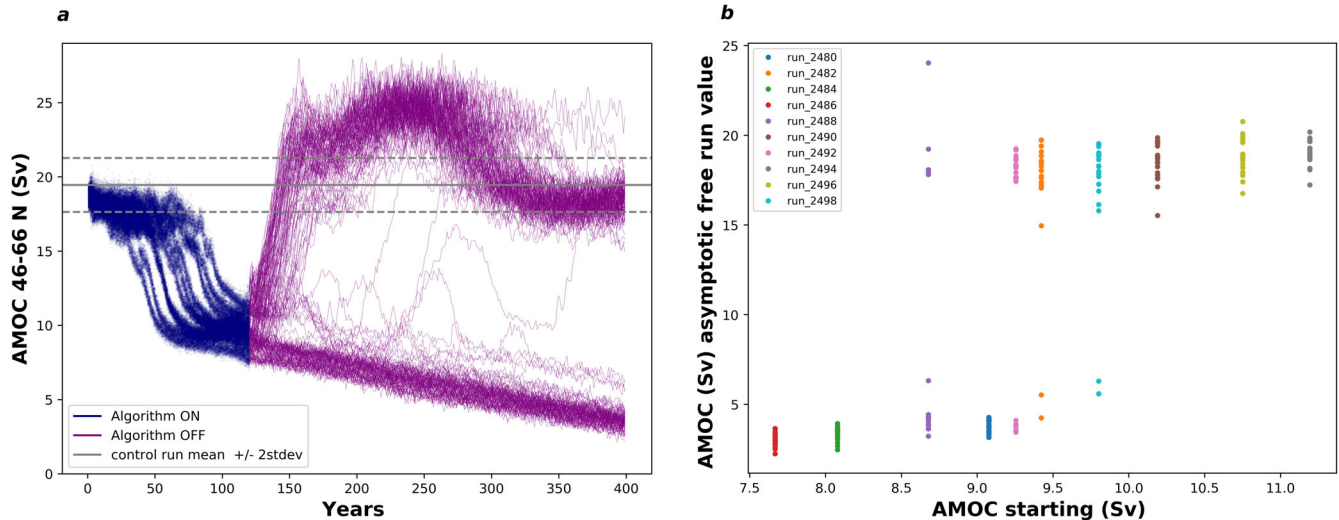

Fig. 4 Evolution of the AMOC in the free-running ensemble. a Evolution of the AMOC (purple lines) in a 200-member ensemble free-running extension of the simulations produced with the rare-event-algorithm (blue points, as in Fig. 1b). The 200 members are composed of ten sub-ensemble of 20 members each. Each of the ten sub-ensembles branches at year 120 from one member of each of the ten simulations performed with the rare event algorithm. Each free-running simulation is run for an additional 280 years. **b** Relationship between the final value of the AMOC (years 390–400) in the free-running simulations vs the value of the AMOC at the time it branched from the rare-event-algorithm simulations, for each of the 200 members.

anomalies in the North Atlantic are by far the most intense signal, relative to the internal variability of the system.

The anomalies in the surface fluxes identified in Fig. 3 might in principle either be the response to or the drivers of the AMOC weakening within the 1-year resampling timescale. However, the zonal wind stress from the intensified jet stream is consistent with an induced weakening of the AMOC via Ekman transport, implying an initial role of the atmosphere in driving the ocean. Indeed, referring to Fig. 3a and following Yao F. et al.[51], we estimate that the intensified jet stream at about 50 N induces a net surface southward Ekman transport at the same latitudes of about 0.35 Sv. This is about 60 to 90% of the anomaly in the meridional overturning stream-function of the cloned members relative to all members in the same latitude range (Supplementary Fig. 5), and it is consistent with the known role of wind stress in driving AMOC anomalies in the interannual and seasonal time scale[47,49,52], and possibly even on a longer time scale[49].

However, a -0.35 Sv anomaly is only a small contribution to the simulated weakening of the AMOC on multi-decadal timescales, implying that density anomalies must eventually dominate the AMOC weakening and its abrupt transition in the rare event simulations. The gradual collapse of the convection over the Labrador Sea, inhibiting dense water formation, is likely to be playing a key role for these density anomalies. Indeed, the collapse of convection precedes the start of the AMOC abrupt weakening events in all the rare event simulations (Supplementary Fig. 6). Note that the simulations in which the convection collapse is slower are associated with a delayed AMOC abrupt transition, and with a higher value of the AMOC index at the end of the simulation. There might be several pathways by which the atmosphere-ocean interactions from Fig. 3, repeated over several decades, may eventually lead to the Labrador Sea convection collapse. The AMOC weakening initiated by wind stress might, via the salt-advection feedback, lead to further weakening, via a reduced surface transport of hot-salty water toward the Labrador Sea (Supplementary Fig. 7). However, it is also possible that the high latitude freshening from precipitation minus evaporation (Fig. 3b) or Labrador Sea surface heating (Fig. 3c), gradually become themselves important in stabilising the water column on multi-decadal time scales. Unravelling the relative role of these processes will require analyses beyond the scope of the paper.

Collapse, recovery, and critical thresholds

In the previous section it has been shown that internal climate variability is sufficient to induce an abrupt slowdown of the AMOC. Now we ask if, after the abrupt transition, the system has tipped into a new stable state in which the AMOC is partially collapsed. This is tested by extending the previous simulations after year 125, but with the rare event algorithm turned off. In order to test the robustness of our finding we generate 20-member free-running ensemble simulations by randomly perturbing the sea level pressure. However, in order to reduce the computational costs, we only extend the first ensemble member from each of the ten rare-event-simulations. This setup leads to a 200-member free-running ensemble, featuring members starting from 10 different initial states.

The evolution of the AMOC in the free-running ensemble is given by the purple lines in Fig. 4a. Two opposite behaviours emerge, revealing a bimodal distribution in the evolution of the AMOC. For some ensemble members, the AMOC clearly bounces and overshoots, before relaxing to its starting value on a timescale of about 200 years. On the contrary, for other members, the AMOC keeps weakening even during the free run. This clearly shows that a noise-induced tipping has been achieved and the system evolves towards a new equilibrium state, at least on a time interval of 400 years. Only three ensemble members are able to pass from the collapsed to the active AMOC states in the course of the free-running simulations.

In the light of the previous results one may wonder what are the climate aspects that determine whether the AMOC would eventually collapse or bounce back. A quantity that is considered fundamental for the behaviour of the AMOC is the AMOC strength itself, as the salt advection feedback implies that a very weak AMOC may not be able to recover. Indeed, other studies tried to determine a critical threshold or at least an indicator of the AMOC future qualitative evolution from the strength of the AMOC itself, though no robust conclusions were found[21,53]. Figure 4b explores this point by showing, for all 200 members, the value of the AMOC at the end of the 280-year free-running simulation as a function of the value at which the simulation started at year 120. All the ensemble members that start with an AMOC weaker than 8.5 Sv evolve towards an AMOC collapse. On the contrary, the AMOC bounces back and relaxes to the control run values in all members
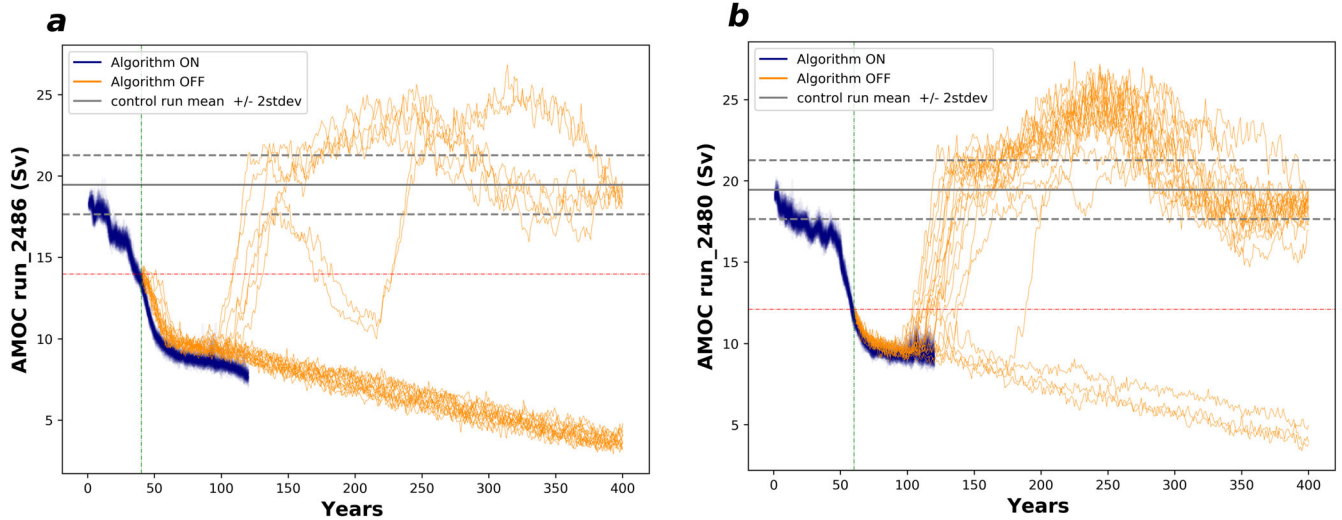

Fig. 5 Example of early start experiment. a The 20 orange lines represent the free-running evolution of the AMOC ensemble members starting at year 40 of run_2486 performed with the algorithm on, which is shown in blue. The green vertical line marks year 40, while the red horizontal line is plotted at 14.00 Sv. **b** As in (**a**) but for the 20 free-running members starting at year 60 of run_2480. The green vertical line marks year 60, while the red horizontal line is plotted at 12.12 Sv.

starting with an AMOC above 10 Sv. Between the two regimes, the evolution of the members is not unambiguously determined, and the same initial condition can either evolve into a collapse or a recovery of the AMOC. Since the different members, for any given starting AMOC, are initialised only via small random perturbations to the sea level pressure, the evolution of the system appears to be unpredictable. This implies the system is close to the edge of the two basins of attraction, and the chaotic atmospheric variability is sufficient to tip it in one state or the other.

These results seem to support the idea that the AMOC strength, consistent with the salt advection feedback, is a key parameter in order to determine the following behaviour of the system. However, when additional experiments are performed, it is found that these thresholds are not robust, rather they seem to be linked to the specific state reached at the end of the rare-event simulations. In particular, for the two rare-event simulations in which the AMOC is fully collapsed at year 120 (see Fig. 4b for runs 2480 and 2486), we performed nine additional "early-start" free-running ensemble simulations initialised before year 120, i.e at years 40, 50, 60,…, 110. The outcomes of the new experiments, though generally consistent with the previous results, reveal two initial conditions for which an AMOC collapse is achieved despite an AMOC starting value greater than 10 Sv. In particular members starting at year 40 of run 2486 (Fig. 5a, starting AMOC strength of 14.00 Sv) and members starting at year 60 of run 2480 (Fig. 5b, starting AMOC strength of 12.12 Sv), having already passed the tipping, show an AMOC abrupt decrease as in the runs with the algorithm on.

The results from all the free-running ensemble simulations (Fig. 6a) reveal that much care is needed before inferring the evolution of the AMOC based on the AMOC value itself. For example, members starting near 14 Sv tend to collapse while the ones starting between 10 Sv and 12 Sv all recover. This is enough to reject the idea of a hard AMOC strength threshold that controls the behaviour of the system. Instead, we suggest that these results imply an increasingly small, but non zero, risk of AMOC collapse even for high starting values of the AMOC. This is consistent with the ability of the rare-event simulations to find internal trajectories leading to a collapsed AMOC starting from the control run at around 20 Sv. On the other hand, we show that there is no evidence of the recovery of the AMOC in trajectories in which the value of the AMOC reaches a value below 7.5 Sv (Fig. 6b). This may be seen as a sufficient, but not necessary, condition to have an

AMOC collapse in PlaSim-LSG since paths to collapse exist well above that value.

DISCUSSION
This work has assessed the possibility of applying a Rare Event Algorithm to the study of noise-induced tipping events in a coupled climate model. We show that the rare event algorithm is able to identify AMOC collapses induced by internal atmospheric variability in the intermediate complexity PlaSim-LSG climate model, thus showing the potential of this approach to explore tipping events in the climate system. The proposed approach can be easily applied to a large variety of phenomena once one has defined the quantity that needs to be minimised or maximised to induce a tipping event. In particular, the algorithm offers the opportunity of generating a large number of tipping events without introducing any external forcing. This can be very useful in studies on tipping points in which it is unknown a priori what may trigger the events, since the trajectories generated with the algorithm can be used to infer the mechanisms driving the transitions.

With the rare event algorithm, we are able to isolate the atmospheric processes initiating the AMOC slowdown from the climate response to the weakened AMOC state. We suggest that an intensified jet stream over the North Atlantic is the initial driver of the AMOC slowdown at the beginning of the rare-event simulation, via the induced oceanic Ekman circulation. Subsequently, after a few decades of atmospheric forcing, a gradual convection collapse in the Labrador Sea leads to an abrupt weakening of the AMOC. Therefore, in the current version of PlaSim-LSG, the repeated occurrence of an intensified jet stream for at least a few decades seems to be sufficient to lead to an AMOC collapse without possibility of recovery on multi-centennial time scales. The process driving the AMOC slowdown is likely to be dependent upon the model used, but at the same time, the applicability of the rare event algorithm to identify such processes in different models is of general interest.

The weakened AMOC found at the end of the 125-year rare-event simulation is itself driving a cooling of Northern Hemisphere temperatures and a strengthening and poleward shift of the Northern Hemisphere jet streams. Precipitation anomalies reveal a southward shift of precipitation in the tropics, consistent with a southward shift of the ITCZ, and reduced rainfall in the North
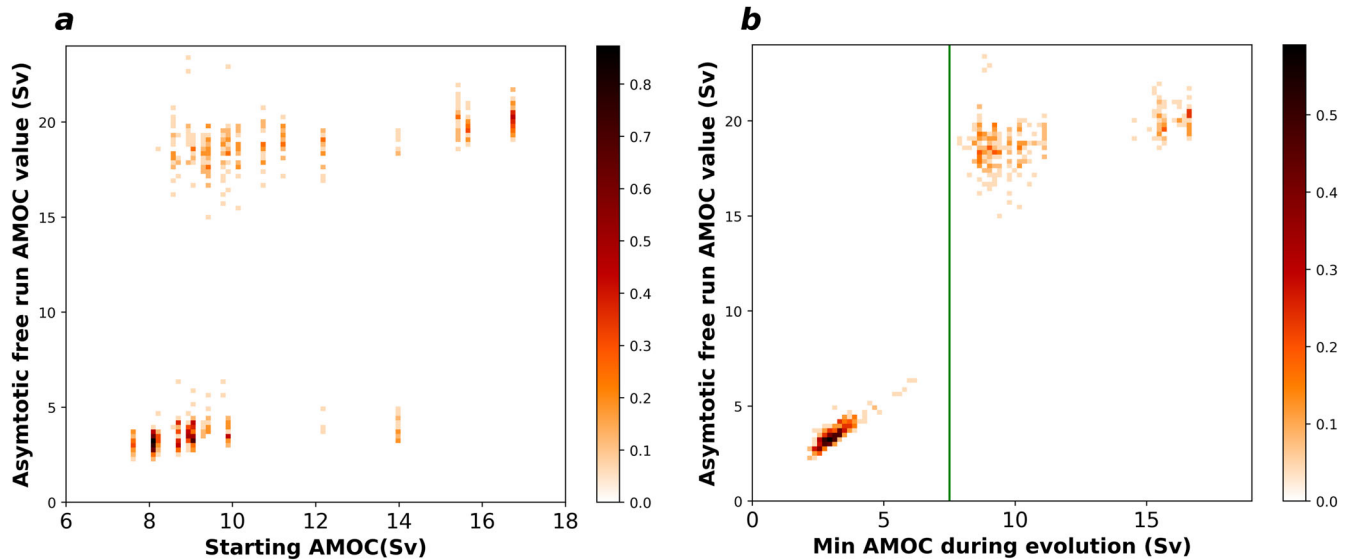

Fig. 6 Challenges in predicting the final value of the AMOC. a As in Fig. 4b, but also including the 18 free-running ensemble simulations initialised before year 120 of the rare-event simulations. Atlantic. These responses are consistent with those found in experiments adopting an external forcing to weaken the AMOC in state-of-the-art climate models[1,5–7,27]. This suggests that the key elements of the response to an AMOC slowdown are already embodied in this simplified unforced context, thus supporting the use of Earth System Models of Intermediate Complexity (EMICs) to analyse these problems.

In summary, we conclude that:

- Rare event algorithms are very promising tools to test the multistability of a system and in particular to sample noise-induced tipping events.
- In PlaSim-LSG, atmospheric internal variability can lead to an abrupt weakening of the AMOC even without external forcing elements, but with an analogous climate response as in externally forced experiments.
- After 120 years of simulation performed with the rare event algorithm, some of these simulations have reached AMOC collapsed states from which the system does not recover in the following 280 years. This implies that the rare event algorithm is able to sample dynamical trajectories linking two meta-stable states of the climate model with different AMOCs.
- The hypothesis that the AMOC value itself could control the following evolution of the system towards the active or collapsed AMOC state is not fully sustained by our data. Indeed, we have not been able to identify universal thresholds on AMOC strength that characterise whether the AMOC will recover. A spontaneous AMOC collapse may happen even for high AMOC initial values (14 Sv in our case). In contrast, when the AMOC crosses a value of 7.5 Sv it is not able to recover anymore.

This study extends the possibility of an AMOC tipping induced by pure internal variability[33] to a general circulation model. Compared to Castellana et al. (2019)[33], who found temporary noise-induced AMOC transitions, we are able to identify multiple full-collapses of the AMOC. This may be attributed to the different algorithm design[54] as well as our use of a coupled climate model that accounts for full variability in the atmosphere-ocean interactions, not limited to freshwater input only. Previously, noise-induced AMOC tipping had been demonstrated in simulations conducted with the GISS climate model under the SSP2-4.5 scenario[31,32]. Our findings extend this possibility to an

unforced control simulation. In our case the AMOC collapse is initially driven by atmospheric variability and the subsequent collapse of convection, rather than the variability associated with sea ice transport and melting[32]. In summary, we think this study contributes to stress the role of internal variability in triggering an AMOC collapse[31–33,55]. Furthermore, we have shown that the strength of the AMOC cannot unequivocally determine the system's evolution, confirming Jackson et al. (2023)[21] and suggesting that the concept of probabilistic "safe-operating space" must be considered in place of the concept of a deterministic control parameter governing the AMOC tipping[56].

If on the one side there is great potential to apply this method to new tipping elements, there are nevertheless several aspects related to internal AMOC tipping events that still need to be better assessed. First of all, the role of the identified driving atmospheric circulation pattern should be tested in a state-of-the-art climate model. Furthermore, the approach presented in this paper could be extended to a system with perturbed GHGs concentration. This would allow to explore the risk of a spontaneous collapse of the AMOC at different levels of global warming.

METHODS

The Climate Model: PlaSim coupled to LSG

We perform numerical experiments using the Planet Simulator[40,41] General Circulation Model (PlaSim) coupled to the Large-Scale Geostrophic Ocean model (LSG)[42,43]. PlaSim-LSG, in different configurations, has been already used in several studies ranging from aquaplanets, to paleoclimatic reconstructions, future climate projections and AMOC variability[11,45,57]. PlaSim is based on the wet primitive equations representing the conservation of momentum and mass, the first law of thermodynamics and the equation of state, simplified by the hydrostatic approximation[44]. PlaSim includes parametrization of sea ice and land processes, as well as a slab ocean model. The slab ocean acts as a thermal bath and water reservoir for absorption and release of heat and freshwater but has no representation of oceanic currents.

LSG is a simple ocean model that accounts for the geostrophic dynamics of the ocean on spatial scales larger compared to the internal Rossby radius as well as on time scales larger compared to the typical period of gravity modes and barotropic Rossby wave modes. The model implicitly solves the primitive equations

neglecting the nonlinear terms in the Navier–Stokes equation. The interaction between PlaSim and LSG occurs through the slab ocean layer of PlaSim (50 m) that determines average 10-day temperature to be used as the uppermost layer for LSG, while average 10-day fluxes of momentum and freshwater are given by the sea ice and atmospheric modules. In turn, the slab ocean of PlaSim is forced to relax towards the uppermost layer of LSG in the following 10 days of PlaSim evolution[11,44].

Following Mehling[45] and Angeloni[44], the coupled PlaSim-LSG model is run at T21 horizontal spectral resolution and 10 vertical levels in the atmosphere, 3.5 deg and 22 vertical levels in the ocean. The state of the AMOC in this model has been shown to be sensitive to the parameterisation of the vertical profile of the ocean vertical (diapycnal) diffusivity, in particular to the value of the diffusivity in the upper layers[44]. In this work we use the values of diffusivity proposed and tested in Angeloni (2022)[44] (see Supplementary Information for further details). The AMOC has a stable behaviour on the millennial time scale, with values between $17-21$ Sv, and multi centennial oscillations up to 4 Sv (see Fig. 1a). Overall, the model shows a satisfactory large-scale climatology given its low resolution, with model biases concerning surface temperature and sea ice cover being mostly confined to the Southern Hemisphere[44]. However, a relevant bias for this study is that North Atlantic oceanic currents don't follow the usual counterclockwise circulation around the North Atlantic subpolar gyre, but subtropical surface water tends to go more directly from the Gulf of Mexico to the strong convective area in the Labrador Sea (see Supplementary Fig. 7 and Fig. 2e grey contours).

Greenhouse gases are taken into account by a single value of CO2-equivalent concentrations, which is kept fixed at 354 ppm. With this CO2 level and diffusivity parameter, Angeloni[44] demonstrated that the model has two AMOC stable states: a state with the already mentioned values of the AMOC and a weak AMOC state of about 5 Sv without oscillations. This makes PlaSim-LSG particularly suitable to explore whether it is possible to find internally driven transitions to the collapsed state from the strong circulation state with the rare event algorithm. In Angeloni[44] no transition from one state to the other during millennial scale simulations have been found.

The use of an EMIC allows us to test our experimental setup, exploring the parameter phase space of the algorithm with low computational cost. It is important to stress that dealing with an EMIC can also be a way to isolate fundamental mechanisms in a given phenomenon. In other words, if we can obtain results comparable to General Circulation Models (GCMs) in a simplified climate model, then the key processes of that phenomenon must already be contained in the simplified model.

AMOC metric

The North Atlantic meridional overturning streamfunction Ψ at latitude θ and depth z, is defined as

$$\Psi_\theta(z) = -\int_{\varphi_{west}}^{\varphi_{est}} \int_{z_{bottom}}^{z} v_v r_T |\cos\theta| d\varphi dz'; \quad (1)$$

where Z_{bottom} is the oceanic depth, v_v the meridional velocity, φ the longitude angle and r_T the Earth radius, φ_{est} and φ_{west} represent respectively the east and west margin of the Atlantic Ocean basin at latitude θ. The AMOC strength is obtained as the maximum of the $\Psi_\theta(z)$ between 46° and 66°N and below 700 m,

$$\text{AMOC} = \max_{z,\theta} \{\Psi_\theta(z)\}_{z>700m, \theta \in 46° - 66°N} \quad (2)$$

The AMOC strength is evaluated at every ocean model timestep (10 days) and then averaged to obtain an annual mean AMOC index.

Application of the rare event algorithm

The general characteristics of the algorithm are described in several works[34–36]. Here, we summarise the key aspects, and describe the implementation adopted for this study (see Supplementary Fig. 1). In this work, an experiment with the rare event algorithm consists of an ensemble of 100 members initialised from slightly different initial conditions, that are obtained by applying small random perturbations to the sea level pressure of the same starting configuration. Each simulation is run for 125 years. At constant intervals of 1 year, which is the resampling time scale of the experiment, each trajectory i is associated to a weight defined as

$$W_i = \frac{e^{k \cdot AMOC_i}}{\sum_n e^{k \cdot AMOC_n}}; \quad (3)$$

where k is a negative parameter (see below) and AMOC is the 1-year average AMOC index during the last resampling time. Before simulating the following resampling time interval, each ensemble member generates a number of clones proportional to its weight. The number of replications of the single trajectory i at step n for the next step $n+1$, is

$$c_{n,i} = \text{integer}[W_{n,i} \cdot N + r_{n,i}], \quad (4)$$

where $integer[\cdot]$ defines the integer part, N is the number of members in each resampling step, and $r_{n,i}$ a random number between 0 and 1. Trajectories with low value of the AMOC index will generate a large number of replicas in the following resampling time (since k is negative), while trajectories with large values of the AMOC index will generate 0 replicas, being effectively killed. The selection and cloning are done in such a way that the number of ensemble members remains constant throughout the integration ($\Sigma_i c_{n,i} = N$). If this condition is not met, the $c_{n,i}$ are adjusted by selecting random members to be killed or cloned.

All the replicas are perturbed with a small random perturbation applied to the sea level pressure. This perturbation, of the relative order of $10^{-4}-10^{-5}$, allows the system to explore the neighbourhood of the phase space. The generated trajectories will diverge from each other during the model simulation, allowing to explore possible alternative evolutions of climate variability starting from the parent trajectory. It should be clear that the small perturbation added is not the driving mechanism for the AMOC decrease rather it is just a way to explore the phase space.

The application of the algorithm will populate the ensemble of trajectories characterised by extremely low values of the AMOC averaged along the entire simulation length. The absolute value of the parameter k, that we remind being negative, determines how stringent the selection is, where the larger $|k|$ the larger the number of trajectories discarded at every resampling step. We explored the sensitivity to the parameter k. The results shown in the paper refer to the parameter k set to -3 Sv^{-1}, but simulations were also performed for $k = -1$ Sv^{-1} and $k = -10$ Sv^{-1}. The results are not discussed in this paper, however, we found that for $k = -1$ Sv^{-1} the selection is so loose that a significant slowdown can't emerge in 125 years, while for $k = -10$ Sv^{-1} the selection is so tight that it can lead to issues involving local minima of the AMOC.

In order to test the robustness in our findings we performed 10 independent ensemble simulations, each with 100 members and 125-year long. The 10 ensemble simulations were initialised from 10 different years of the control run in the period 2480–2500 with a 2-year interval, i.e., 2480, 2482, 2484, 2486,…, 2498.

Triggering mechanisms

The algorithm selects and clones trajectories at the end of every 1-year resampling time interval. The driving mechanisms able to induce a weakening of the AMOC in a time scale of one year are

statistically preferred to those that develop in a longer time scale. Considering that the dynamical evolution of the atmosphere is much faster than the one of the ocean, the initial driving mechanism of the AMOC slowdown must mainly resides in atmospheric signals which are subsequently transferred to the ocean. Each ensemble member, due to the chaotic nature of the atmosphere, will evolve in a different trajectory, leading to different impacts on the AMOC.

The mechanisms driving the AMOC slowdowns are evaluated by examining the difference in the annual-mean climate between the ensemble members that are replicated versus the full set of ensemble members, where the signal of the replicated members is weighted over the number of replications generated for the following resampling time step. This difference is computed for every year, and then averaged over the whole simulation. Finally, the mean difference is scaled by the internal variability of the system measured in sigma units. The internal variability is computed as the average standard-deviation of annual-means over the full set of ensemble-members. Thus we are able to compare the relative size of the anomalies across different observables. In summary, if A is an annual-mean quantity,

$$A_{\text{driving}} = \frac{1}{\text{years}} \cdot \sum_n^{\text{years}} \frac{[A]^{(n)} - \langle A^{(n)} \rangle}{\sigma^{(n)}}, \tag{5}$$

where

$$[A]^{(n)} = \Sigma_i^{\text{members}} A_i^{(n)} \cdot c_i^{(n)}, \langle \psi \rangle = \Sigma_i^{\text{members}} \frac{\psi_i}{\text{members}}, \sigma^{(n)} = \sqrt{\left\langle \left(A^{(n)} - \langle A^{(n)} \rangle \right)^2 \right\rangle}$$

members $= 100$, years $= 125$.

DATA AVAILABILITY
Relevant dataset generated and analysed during the current study is available at https://doi.org/10.5281/zenodo.10361524. Full dataset is anyway available from the authors upon request.

CODE AVAILABILITY
Scripts for the data analysis are available at https://doi.org/10.5281/zenodo.10361524. The large deviation algorithm is available at https://zenodo.org/records/4763283. The version of PlaSim-LSG model is available at https://doi.org/10.5281/zenodo.4041462 and at https://github.com/matteci/PLASIM_LD.
