Globalization challenges sustainability by intensifying the ecological and economic impacts of biological invasions. These impacts may be unevenly distributed worldwide, with costs disproportionately incurred by a few regions. We identify economic cost distributions of invasions among origin and recipient countries and continents, and determine socio-economic and biodiversity-related predictors of cost dynamics. Using data filtered from the InvaCost database, which inevitably includes geographic biases in cost reporting, we found that recorded costly invasive alien species have originated from almost all regions, most frequently causing impacts to Europe. In terms of cost magnitude, reported monetary costs predominantly resulted from species with origins in Asia impacting North America. High reported cost linkages (flows) between species' native countries and their invaded countries were related to proxies of shared environments and shared trade history. This pattern can be partly attributed to the legacy of colonial expansion and trade patterns. The characterization of 'sender' and 'receiver' regions of invasive alien species and their associated cost can contribute to more sustainable economies and societies while protecting biodiversity by informing biosecurity planning and the prioritization of control efforts across invasion routes.

Anthropogenic global changes challenge the conservation and sustainability of natural and economic systems¹. Trends such as human population growth, intensifying international trade and travel, and growth of material transport networks may accelerate ecological, social and economic impacts of environmentally destructive practices^{2,3}. Consequently, future economic growth could be offset by a growing monetary burden attributable to global change^{4,5}. However, these impacts may be unevenly distributed around the globe^{6–8}. A potential

Invasive alien species (IAS)–defined in a management context as species introduced outside their native range as a result of anthropogenic activity and which have harmful effects–are among the main threats to biodiversity, biogeographic relationships and ecosystem functioning worldwide^{3,9}. In addition to ecological impacts, the economic impacts of IAS and their related capacity to undermine human and social wellbeing are burgeoning^{5,9}. IAS weaken progress towards many of the United Nations Sustainable Development Goals¹⁰. With rapidly growing invasion rates worldwide⁸, the magnitude of these impacts is expected to increase further in the future¹¹. While not all impacts can be easily monetized¹², prominent ones include costs to human healthcare systems, production enterprises (agriculture, fisheries, aquaculture, forestry), tourism and real estate, human-made infrastructures and ecosystem services^{9,13,14}.

Recent syntheses of invasion costs have shown that reported costs of IAS vary hugely across geographic regions⁵ (for example, three orders of magnitude among European countries¹⁵). Regional variability in incurred costs is probably attributable, among other reasons, to the extent of connectivity to the rest of the world through trade and transport networks^{2,16}, differences in introduction pathways^{17,18}, the scale and type of economic activity¹³ and any ecosystem resistance to invasions conferred by local biodiversity¹⁹. Additionally, factors such as research effort contribute to regional variability in reported costs¹¹, while publication language influences their inclusion in syntheses²⁰.

In our increasingly globalized world, sustainable development depends on understanding the interactions between geographically disparate human-natural systems²¹. In the context of biological invasions, this means understanding the flows of IAS and their effects among regions. However, research has tended to focus on IAS flows without extending to examination of resulting impacts^{22,23}. There has been no research thus far that identifies sender and recipient regions, or the structure and determinants of flows among them, in the context of impacts caused by IAS. We focus on monetary impacts and define 'sender' regions as those from which IAS originate, and 'recipient' regions as those invaded and where costs occur. Note that sender regions are not necessarily responsible for the subsequent invasion and its impacts; rather, they are simply part of the native range of these IAS. For simplicity, we describe the costs associated with the movement of IAS from a particular origin to a recipient region as 'flows' (while we acknowledge that it is the IAS that flow) to emphasize the inherent linkage of species movement to cost dynamics.

An understanding of how impacts of globalization, and specifically costs of invasions, are distributed across space and time could contribute to sustainability in multiple ways. For example, it could identify regions that disproportionately suffer costs from invasions due to the uneven impact of trade activities with distant nations. Similarly, it can identify inequalities—such as continents, countries or other regions that are net receivers of IAS and their costs, or with low research capacity relative to the invasion pressure they face—that should be addressed to meet the Sustainable Development Goals (for instance Goal 10 (ref. 24)). It could also highlight opportunities for prioritized biosecurity actions, such as risk screenings for imported goods or early-warning surveillance systems for potentially costly IAS from specific origins. Identification of socio-economic and environmental predictors of invasion costs could also help to inform proactive management²⁵.

The InvaCost database (Supplementary Note 1) documents globally reported monetary costs of IAS. Notwithstanding known regional biases in the reporting of costs, it allows comparisons of standardized costs at taxonomic¹¹, sectoral¹⁵, regional¹⁵ and global levels⁵. To investigate the spatial distribution of senders and receivers of sustainability challenges triggered by invasions, we quantify the monetary burden within and flowing between sender and recipient regions (continents or countries). Specifically, we examine: (1) whether some continents or countries send or receive a disproportionate amount of economically costly IAS and costs associated with those IAS; and (2) whether socio-economic and environmental variables predict cost flows between country pairs.

Results

Continent-level patterns

Numbers of IAS sent and their reported costs were unevenly distributed across continents (Fig. 1). Note that the same was true for reporting effort, and that our results should be interpreted with this in mind (Fig. 1a). Together, the Northern continents (Europe, Asia and North America) both sent (67%) and received (66%) the majority of IAS. 'IAS' here, and throughout the results, refers only to non-domesticated species, with costs in the InvaCost database and for which we could identify \geq 1 native continent or country (Fig. 2, see Methods). The Northern continents also sent 82% and received 95% of the total reported invasion cost in our dataset (US\$467 billion from 459 IAS; all costs reported herein are in 2017 US\$). Our dataset did not contain any costs attributable to single species in Antarctica.

Asia sent the largest share of IAS (29%), followed by North America, Europe, South America, Africa and Oceania (Fig. 1b). Europe had the greatest share of IAS received (40%), followed by Oceania and North America. Other continents received under 10% of IAS. Asia sent three times more IAS than it received, while Africa, North America and South America were also net IAS senders. Both Europe and Oceania were net receivers of approximately three times more IAS than they sent. All continents received flows of IAS from all other continents, except for Asia which did not receive IAS from Oceania (Fig. 3a). There were particularly large flows from Asia and North America to Europe.

Compared to the pattern in the flow of IAS, the pattern of reported costs was more unevenly distributed among continents (Fig. 1). Seventy percent of reported costs were sent by (that is, due to species native to) Asia and 13% by Africa, with the remaining continents each sending below 10% of total reported costs. Most reported costs were received in North America (82% of received costs, predominantly from Asia; Fig. 2b and Extended Data Fig. 1), followed by Asia. The remaining continents each received 3% of reported total costs or less. Accordingly, most continents were net senders of costs (Fig. 1c): Africa and Asia sent over seven times more costs than they received, while Europe and South America were also net cost senders, by about twofold. Conversely, North America received 18 times more costs than it sent, and Oceania was also a net receiver by twofold. As for species, reported costs flowed between all pairs of continents, except from Oceania to Asia (Fig. 3b).

These regional patterns were similar when accounting for research effort (number of publications in our dataset) as a simple proxy for capacity to report IAS costs, although South America became a net receiver (Fig. 1d). Furthermore, these patterns are relatively insensitive to additional data, as substantial increases in research effort would be required to override these results (446–1,677% to override the top sender and 729–5,267% to override the top receiver; Supplementary Table 1). While we do not focus on temporal trends, we note that across continents, species and reported costs (both raw and per publication) sent and received tended to increase over time (Supplementary Note 2 and Extended Data Figs. 2–4). Reported cost flows among continents according to cost types and activity sectors are shown in Supplementary Tables 2 and 3.

Country-level patterns

The country sending the most reported costs was China (US\$279 billion, US\$1.6 billion per publication reporting costs due to Chinese-native species; Fig. 4a and Extended Data Fig. 5a), substantially exceeding other sender countries. The country receiving the most reported costs was the USA (US\$339 billion, US\$2.8 billion per publication reporting costs incurred in the USA; Fig. 4b and Extended Data Fig. 5b), although

(**d**) associated with continent pairs, for IAS sent and received by each continent. Costs are in 2017 US\$ millions. Percentages in **b** and **c** correspond to the share of the total per region. Credit: base map created with Wikimedia Commons (public domain).

it was second to Colombia when considering reported cost per publication (US\$3.3 billion). Several countries appeared as both top senders and receivers (China, Canada, Colombia, USA, Australia, Russia; Canada and USA only when considering reported cost per publication).

The strongest pairwise flow of reported IAS costs was from China to the USA, amounting to US\$275 billion or 99% of the total reported cost from China to other countries (Fig. 4c and Extended Data Fig. 5c). Six of the top 10 pairwise relationships included the USA at the receiving end (7 when corrected by research effort). South Africa was a top receiver of costs from Australia (for raw reported costs only), while Canada was a top receiver from China, and China was a top receiver from Brazil and Colombia (for both raw reported costs and cost per publication). The top 10 was very similar when considering cost flows per publication (Extended Data Fig. 5). Additional analyses including species without country-level origin information changed the top 10 receiver countries, resulting in several more entries from Asia (Supplementary Fig. 1).

Of the 223 countries in our dataset, only 17 were net receivers (that is, reported costs incurred from IAS in these countries were greater than reported costs of IAS native to these countries). The largest net receivers were the USA (US\$335 billion), Canada (US\$10 billion) and the Philippines (US\$2 billion). There was at least one net receiver country on every inhabited continent. The other 206 countries were net senders (that is, reported costs of IAS native to these countries were greater than reported costs incurred from IAS in these countries);143 of these sent costs without reporting any costs received, while 63 both sent and received costs. The largest net senders were China (US\$274 billion), India (US\$23 billion) and Mexico (US\$4 billion).

Predictors of cost flows

A wide range of environmental and socio-economic variables were predictive of the value of cost flows between sender and receiver countries, with differing effect sizes. Significant positive predictors of pairwise cost flows were: total reported cost sent (by sender country), latitude (of receiver country), country area (sender and receiver), distance between countries, number of species involved, shared biome, common language and shared colonial history. Significant negative predictors of pairwise cost flows were: research effort (in sender country), human population and road density (in receiver country), primary industry values added (in sender and receiver), and pairwise trade volume and presence of a free-trade agreement (Fig. 5). These effects were largely similar when accounting for research effort as cost per publication and testing sensitivity to increased non-USA data and weighting of cost flows across multicountry origin regions (Supplementary Figs. 3–6).

Discussion

Invasive alien species causing economic costs have originated from and invaded all inhabited continents globally. This worldwide problem challenges sustainable development and requires urgent international cooperation for effective mitigation. While known regional research biases underlie cost flows, particularly large numbers of IAS with reported costs have been sent from (that is, are native to) Asia and North America, and received in Europe and Oceania. Sender-recipient dynamics for reported costs have been dominated by Asia as the main sender and North America as the main receiver. Only 17 countries were net receivers of reported costs, with the USA being dominant among these. It is notable that Asia sends a relatively large reported economic cost (5-70 times that of other continents) relative to the number of IAS it sends (only 1-4 times the other continents). Similarly, North America receives a far greater reported cost (8-54 times that of other continents) than would be expected given the number of IAS it receives (0.4-2.6 times the other continents). These patterns probably reflect a complex, interacting mixture of influences such as trade volume and direction, the identity of species sent and received, and publication language.

Trade and economic impact dynamics

While our cost data are recent (1960-2020), invasion dynamics can exhibit considerable lag times often spanning many decades²⁶, hence current sender-recipient dynamics probably reflect historical patterns of trade and colonialism¹⁶. Contrary to our expectations, cost flows were significantly negatively influenced by trade volumes in the 1990s and 2010s. However, many of the largest reported cost flows were between major contemporary trading partners. For instance, Asia's share of global exports rose from 15% in the 1970s to 36% in 2010²⁷. For the USA, costs received from China and India were pervasive, perhaps reflecting import dominance from these rapidly developing economies over recent decades, driven by the USA's consumption-based economy²⁸, flows of immigration for intentionally introduced invasive species²⁹ and/or regional cost reporting biases owing to underlying differences in research capacities among countries. Indeed, countries such as the USA were both high net importers and received high costs, whereas China bore much lower reported invasion costs relative to trade (Extended Data Fig. 6 and Supplementary Note 3).

Cost flows displayed similarities and differences to global alien species flows. Invasion cost flows corroborate dominant plant movements from Asia and Europe to North America, for example¹⁶. Similarly, flows of alien reptiles have largely been from Asia and Africa to the Americas, but flows of alien amphibians have largely been between the Americas and within³⁰. Alien aquatic macroinvertebrates in North America often originate from the Ponto-Caspian region in eastern Europe/western Asia³¹. As with alien species flows, bridgehead effects might distort direct economic impact flows between origin and recipient regions²³. At the country level, our cost flows corroborate previous research highlighting the USA as the largest recipient of IAS, and China and India as the largest senders globally³².

While previous studies have examined the spread and establishment dynamics of IAS², they have fallen short at predicting impacts or considering sender-recipient dynamics of these impacts. An increase in invasion rates and socio-economic impacts is expected to accompany

future economic growth^{2,15}. For example, northeast Asia's gross domestic product (GDP) is expected to increase 21-fold by 2050². These shifts could result in regions transitioning from net senders to receivers of costs if they become more import-dominant. It is also probable that future changes in country-level research capacities to document biological invasion costs will influence the recorded dynamics of their senders and receivers.

Socio-economic and biological predictors of cost flows

Our cost flow results have clear implications for biodiversity conservation and policy. Previous studies have shown that invasion dynamics are shaped by importation volume and species richness³³, as well as national wealth and human population density³⁴, suggesting that unsustainable wealth generation and human population growth have contributed substantially to biological invasion rates. However, no previous studies

Fig. 4 | **Top 10 senders and receivers. a**-**c**, Top 10 IAS cost sender countries (**a**), top 10 IAS cost receiver countries (**b**) and top 10 sender-receiver country pairs (**c**) in the InvaCost database. Costs correspond to total reported invasion impacts in 2017 US\$ values of species native to a country across all receiving countries (**a**); total reported invasion costs per country, attributable to individual species native to any other country (**b**); and reported invasion costs incurred per receiver country, attributable to species native to the corresponding sender country (**c**).

In c, darker red hues indicate greater senders of costs, darker blue hues indicate greater receivers of costs, and blacker hues represent countries that both receive and send high costs. Countries are not to scale. Arrows indicate species' known native ranges and final recipient regions of costs, and therefore do not necessarily indicate direct flows between countries. have examined pairwise flows in the context of invasion impacts, despite the fact that IAS impacts are independent of invasion success³⁵.

We found greater cost flows between country pairs that share at least one biome, indicating that invasion impacts are greater at lower environmental distances. This finding supports the prioritization of measures to limit propagule flow among regions of the greatest environmental similarity. In contrast, we found that cost flows were larger between physically distant countries, perhaps because physical distance increases the likelihood of ecological novelty and invasion impact. While demonstrated at the level of IAS establishment^{19,33}, we did not find support for biotic resistance influencing reported IAS economic costs, since species richness in the recipient country was not significant. Environmental drivers of IAS impacts may therefore be superseded by socio-economic factors. We found lower pairwise cost flows into countries with larger human populations. We note that this does not necessarily discount high total costs in these areas, as in ref. 33, if supplied by a greater number of sender countries. Although what may be driving this population trend remains unclear, it is possible that these countries may have more capacity to respond proactively to invasion risks and/or may represent larger urban areas where both native biodiversity and heavily invasion-impacted industries, such as forestry and agriculture, are less prominent. Alternatively, it could reflect the influence of substantial human populations in emerging economies (such as India, Brazil and China), whose export-driven trade patterns or lesser research capacities may limit the costs received and reported.

The number of IAS with costs sent and country surface areas were significant positive terms in our model, suggesting that future

Fig. 5 | **Variable importance in the GAM pairwise cost flow model.** Variable importance is indicated for log-scaled country-level cost flows with log-scaled predictors, as measured by each parametric term's *t*-statistic (Supplementary Table 4). The smoother for Decade had empirical degrees of freedom of 3.40 and P < 0.0001 (Supplementary Fig. 6). The overall model had 26.2% deviance explained (n = 5,362). The red line represents an effect of 0, more significant positive effects are shown to the right of the plot, while more significant negative effects are shown to the left (log-log slope terms are shown in text for each bar). Log-log slopes are to be interpreted as the exponent of a power-law relationship, hence a doubled value of the associated predictor would result in 2^b times the cost flow, where *b* is the associated parameter estimate. Non-significant terms are shown in darker blue. All models displayed a 'worst-case' concurvity value below 0.8, indicating that they were not overfit.

increases in invasion rates will drive higher costs and that larger countries will receive and send greater costs¹⁵, despite country area previously demonstrating no clear influence on the degree of invasion in recipient countries³³.

We found that wealth (proxied by gross capital formation) had a non-significant relationship with cost flows, while the values added by primary industries in sender and recipient countries were negative predictors. The negative relationship between value added and cost flow in both directions suggests that primary resource-producing countries are relatively less involved in IAS cost flows in general. Previous studies have found that GDP does not necessarily determine the degree of invasion at the national scale³³.

One might have expected recipient country road density and free trade to increase cost flows between countries, but we found the opposite result: high road densities and free-trade agreements were associated with lower reported pairwise flows of IAS costs. This does not preclude there being higher total cost to these countries if they receive more pairwise flows. Alternatively, countries with lower road densities could incur greater cost flows if these represent more isolated, pristine regions that are vulnerable to IAS. Free-trade agreements could be markers of greater surveillance and oversight capacity, which could reflect greater international cooperation to mitigate invasion impacts. This could ultimately reduce the number of unintentional invasions and/or invasions by species known to have high economic impacts and therefore placed on blacklists or watch lists, leading to lower cost flows¹⁸. Alternatively, this finding could reflect the fact that wealthier countries have both higher numbers of free-trade agreements and greater invasion management capacity. Regions sharing trade agreements may have also had more historical invasions whose costs were incurred before 1960. The negative effect of twentieth and twenty-first century trade on cost flows additionally differs from the positive effect of historical trade on invasion success previously reported²⁶, although our earliest trade period (1995-1999) is relatively late in this century.

Finally, we found more intense flows between countries that shared a language and colonial history. This may be a marker for human movements, such as colonialism and nineteenth or twentieth century trade, that have transported invasive propagules³⁶. A more granular analysis of the role of such factors is an important area of future research.

Data gaps and caveats

It is important to highlight and caveat factors that may have strongly influenced the trends exhibited in the present study. We provide more detail on the following factors in Supplementary Note 4.

First, InvaCost is dependent upon costs reported in original studies, and such reporting of economic costs of biological invasions is distributed highly unevenly both geographically and taxonomically⁵, and frequently lacks specificity. Indeed, costs in InvaCost are known to be skewed towards just a few well-studied taxa in certain places⁵, with several hyper-costly species likely to disproportionately influence global trends and with massive data gaps for other known damaging IAS³⁷. Publication biases undoubtedly influence cost flows, whereby particularly high levels of reporting of impacts in North America could have emanated from relatively early efforts to report invasion costs in the USA, which prompted further research into the effects on the economy in the past two decades³⁸. We aimed to address this descriptively and statistically by including research effort and number of IAS as individual terms across countries and regions. Hence, all environmental and socio-economic effects can be considered in the context of research effort and invasion rates, and are thereby over and above the strength of these terms. We also present reported costs corrected for research effort in our dataset. However, we caution that our proxies probably do not capture all aspects of regional capacities to report IAS and their impacts, and therefore our results are probably still influenced by differences in reporting capacity.

Second, publication language may influence perceived cost flows, where regions with greater reporting effort in common languages (English), such as North America, are better represented in our dataset. Although updates to InvaCost now include data in 21 non-English languages, regions such as Asia and Africa remain heavily underrepresented, with numerous countries having no costs in InvaCost²⁰. While our analyses accounting for research effort would have controlled for some of these biases, they could not account for entirely missing data.

Third, purchasing power affects the cost of damage and management incurred by a region; all else being equal, regions with higher purchasing power (such as Asia, Europe and North America) would inherently incur higher costs. Given this inherent bias and the probable link between lower economic output and research capacity, invasion costs from lower-income countries are probably particularly underestimated. Therefore, research investments in low-to-middle income nations should be promoted to bridge these gaps and support biosecurity.

Fourth, socio-cultural factors will also change the likelihood of invasion management in ways we cannot capture in this analysis. For instance, impacts on ecosystems and health are difficult to monetize, but are also a key motivator for management action⁹. Considering differences in research effort, it is likely that capacities to report costs from ecosystem-based impacts are particularly limited in countries with lower research capacities.

Fifth, we do not account for the many IAS of unknown origin, or for the precise invasion trajectory taken by each one. It is possible that IAS with costs in a receiver region did not originate directly from the species' native region, but rather from 'steppingstone' regions that had already been invaded^{23,39}. This phenomenon challenges the precise attribution of economic cost sources, with invasions potentially caused by trade patterns that are spatially and temporally independent of the initial origin region and of direct trade between senders and receivers. It was impossible to account for this phenomenon in our analyses given the absence of information on invasion trajectories for most species. Our results call for more systematic data reporting and collation, in particular, on species' native ranges, initial source populations of invasive propagules, invasion trajectories, invasion pathways and invasion costs. Future extrapolation efforts could also help to resolve unreported costs. We highlight specific areas for focused research (for example, pathways and vectors involved in cost flows from China to the USA) to provide a basis for future predictions of how negative economic impacts from burgeoning biological invasions will unfold.

Outlook

This work can help promote international cooperation to mitigate economically damaging IAS. Our results should be considered in the context of uneven regional research efforts to report the impacts of IAS and should not be used to support unnecessary economic barriers among countries (such as from the Global South). Identification of major donor regions for costs nevertheless allows prioritization of species sources in early-warning systems to prevent future impacts, which complements pathway determination for informing management¹⁸. Our links among physical distance, socio-economic variables and IAS cost flows suggest that decreased reliance on distant resources in favour of developing local resources could decrease flows of costly IAS. Our results suggest that biosecurity efforts should be prioritized for trade between Asia and North America, and for trade linking several regions to Europe, but that research capacities should be improved to globally report invasion costs and inform on their impact dynamics. IAS economic cost considerations could become an additional factor to include in designing international trade treaties as well as legal frameworks and policy targets for biodiversity protections. Due to the cost and missed economic opportunities associated with decreasing exports, which may dissuade any individual nation from increasing their export-level restrictions, an international governing body for biosecurity may be better positioned to assess risks associated with global trade to decrease biological invasions.

Methods

Cost data and processing

We extracted cost data from the latest version of the InvaCost database (v.4.1, publicly available at https://doi.org/10.6084/ m9.figshare.12668570 (refs. 20,40)). InvaCost has been generated following a systematic standardized methodology to collate invasion costs from peer-reviewed scientific articles, official reports, grev literature, and stakeholder and expert elicitation. Following a thorough and hierarchical screening of each source document for relevance, costs were extracted, standardized to a common currency (2017 US\$) and adjusted for inflation through the Consumer Price Index (https:// data.worldbank.org/indicator/FP.CPI.TOTL?end=2017&start=1960) to be comparable across space and over time⁴⁰. Costs were categorized under a range of descriptive fields pertaining to the original source (such as title, authors and publication year), spatial and temporal coverage (such as period of estimation and study area), cost estimation methodology (such as method reliability and acquisition method) and the cost estimates per se (such as nature and typology of cost relating to damage and/or management costs). Detailed information on all descriptive variables can be found in an online repository of the InvaCost database (https://doi.org/10.6084/m9.figshare.12668570, 'Descriptors4.1.xlsx').

Costs can occur over varying periods; for example, a one-off cost associated with a one-time eradication effort versus a multiyear cost associated with recurrent, annually estimated damages to crop production. To homogenize the temporal occurrence of these cost entries in the database, they were all converted to annual costs using the 'expandYearlyCosts' function of the invacost R package⁴¹. This function provides annualized cost estimates for all entries on the basis of the probable starting and ending years of the cost occurrence provided in the database ('Probable_starting_year_adjusted' and 'Probable_ending_year_adjusted' columns). For example, a single cost entry of US\$5,000 that occurred between 2000 and 2009 would be transformed to 10 entries following expansion, each amounting to US\$500 per year. Accordingly, if costs are reported over a multiannual period, the total cost over that given period is divided by the number of years, resulting in an equal annual cost per year that does not inflate the overall cost. Accounting for these dimensions of costs also allowed for assessments of the dynamics of cost occurrence over time⁴¹. Furthermore, for this analysis, we considered costs with impact years between 1960 and 2020, given limited InvaCost data before 1960 and constraints on the availability of relevant socio-economic variables beyond this period (see 'Predictor variables').

We further considered species-specific cost entries only, thus excluding those for diverse (where costs were reported collectively for multiple taxa) or unspecific (where species-level information was missing) taxa, where 1,557 or 11.6% of entries were excluded (Supplementary Fig. 1). Likewise, we removed costs reported in unspecified geographic regions (those that could not be attributed to any continents or countries) and blank cost entries. We additionally removed cost entries for disease agents (viruses, bacteria and human pathogens) from the data, as these taxa are equivocally identified as alien, and we are typically more interested in the movement of their vector species. For example, invasive alien mosquitoes (Aedes spp.) would be included, while the viral diseases they vector (yellow fever, Zika, chikungunya and so on) would be excluded. We also opted to use the most robust subset of these resulting data by considering only costs that were of high method reliability (from peer-reviewed literature or other sources with documented, reproducible and traceable methods) and were empirically observed (costs actually incurred, rather than expected or predicted). Further, we removed cost entries at the 'unit' spatial scale (belonging to various minor scales below the site level, for example, per m²). This scale has a higher likelihood of being duplicated with costs at larger geographic scales through nesting (for example, unit-level costs might already be captured in an overlapping site-level cost). Further, the total area over which these costs were incurred was variable and often unreported (for example, costs reported per m² without indicating the total size of the area impacted). These filters thus allowed us to consider costs (1) from individual IAS in defined recipient continents or nations and for which regional origins could, in theory, be determined, (2) that were actually incurred, reported and estimated through 'highly reliable' methods and (3) at appropriate, distinct spatial scales. The aforementioned filters, however, also mean that our reported costs are underestimated and uneven due to regional reporting differences. Unless specified differently, all results are provided for the filtered dataset, which represents 30.3% of all Inva-Cost records for continent-level analyses and 27.2% of all records for country-level analysis (see 'Species origins' and Fig. 2 for more details).

Species origins

As a first step in determining species' countries of origin, we employed a web scraping script to gather data from the Centre for Agriculture and Bioscience International (CABI) Invasive Species Compendium (ISC, www.cabi.org/isc), the International Union for Conservation of Nature (IUCN) Global Invasive Species Database (GISD, http://www. iucngisd.org/gisd/) and the Global Biodiversity Information Facility (GBIF, www.gbif.org) (see https://doi.org/10.5281/zenodo.7778972 for more information). CABI's ISC contains a variety of information on IAS around the world, including their current distribution and countries of origin¹⁸. Our script searched using the species names as entered within InvaCost (harmonized using the GBIF.org Backbone Taxonomy⁴⁰), as well as synonyms in the Integrated Taxonomic Information System (ITIS) database via the taxize R package⁴². If a species match was found within the CABI ISC, we searched for a 'Distribution Table' portion of the species entry. If found, we extracted country or region (within country) names tagged as 'Native' within this table.

GISD contains geographical information for many IAS and was used as an alternative to CABI where distributional data were missing. Our script searched for GISD distributional data points tagged as 'Native' and compiled them at the country level. Finally, we checked for matching entries in GBIF (a global database of all types of species distribution) tagged as 'Native' at the country level within the 'occ_search' function of the rgbif package v.3.6.0 (ref. 43). We used present-day political border definitions for each country as defined by ISO3C codes in the countrycode package⁴⁴.

Next, where possible, we used country-scale origins to infer continental origins. Countries designated in InvaCost to be part of Central America were assigned to North America (and we refer to them henceforth as North America). Following InvaCost protocols, overseas territories were linked with the continent that matched their geographic, rather than political, designation. As exceptions, Turkey and Russia were identified as multicontinent sender and recipient countries. Origin continents within Turkey and Russia were selected on a case-by-case basis for each species, considering published data on the finer-scale distribution of each species within these countries as well as the continental designation of other countries listed (for example, if all other origin countries listed were European, we considered the native range to be European; see Supplementary Table 5 for details of species impacted). In these two country cases, we classified recipient regions on the basis of human population because of the role of humans in transporting IAS⁴⁵ and incurring economic impacts¹⁵. Since most of Turkey's population is in Asia and the majority of Russia's population is in Europe, we assigned them accordingly to these continents. As a third exception, China's Special Autonomous Regions (Hong Kong and Macau) and Taiwan were merged with mainland China due to them representing a much smaller landmass, as well as being strongly linked to China politically, economically and geographically.

All origin assignments were checked manually by co-authors (where we ensured that there existed \geq 1 reliable source(s) that agreed on the origin continent at least) or were entered for the first time when information was unavailable from GISD and CABI, using available literature and databases. Literature was identified through ad hoc informal searches, so it is possible that some known native countries were missed. However, this is likely to be a small issue compared with the number of native countries that have never been identified in the literature. A list of literature sources used to check the species' origins is provided in Supplementary Note 5. Some species were allocated only to a continent of origin due to the absence of country-level data (see later).

Origin information was identified for 467 unique species with cost records that met our aforementioned filters (high reliability, observed records within defined continents, cost incurred in 1960–2020, non-pathogens). Of these, eight were removed due to a domesticated status: cat (*Felis catus*), dog/wolf (*Canis lupus*), sheep (*Ovis aries*), dromedary camel (*Camelus dromedarius*), pig (*Sus scrofa*), horse (*Equus caballus*), donkey (*Equus asinus*) and goat (*Capra hircus*); and with cow (*Bos taurus*) and ferret (*Mustela furo*) having been removed by previous filters. This set of species does not have clear native ranges due to their long domestication and/or hybridization history. In contrast, we opted to retain species, such as the European rabbit (*Oryctolagus cuniculus*), with a well-defined native range⁴⁶. The remaining 459 unique species were recorded in six origin and recipient continents, amounting to 4,107 cost entries reported across 539 independent publications (expanded to 8,060 total entries; Fig. 2).

When subset to entries with a country-level resolution, our dataset was further restricted to 412 unique species in 223 origin and 80 recipient countries, corresponding to 3,685 raw cost entries, 436 unique publications and 7,112 expanded entries. Overseas territories were removed from this portion of the analysis because they lacked trade volume, GDP and/or population data, which were implemented in models (see 'Predictor variables').

Impact distributions

Our analyses illustrate the distributions of both (1) numbers of IAS with costs and (2) monetary costs, each among sender and recipient regions. Therefore, our analysis of IAS flows considers only those with reported costs in InvaCost, For (2), we further qualified the costs per region by dividing the total costs by the numbers of publications reporting them, as one way to account for research effort, in a separate analysis. For (1), each species' contribution was divided by the number of origin regions known for the species and/or destination regions recorded in InvaCost. This ensured that each species' contribution summed to '1' in the total number of species sent or received³¹. For example, if a species was native to three countries and was reported to cause impacts to two countries in InvaCost, it would contribute a value of 0.33 species sent from each country and 0.5 species received to each country. We acknowledge that this may not be an accurate representation of the weight of particular origins of the invasion, but this information was unavailable given the complexity and changeability of pathways and vectors. For costs, when a single cost entry was reported in two or more geographic regions or countries, the cost was split equally among those recipient regions or countries. Similarly, if an IAS originated from two or more origin regions or countries, the aggregate cost from that IAS was split equally among those origin regions or countries.

Predictor variables

We separated our analysis by decade. Then, from InvaCost v.4.1, we generated a variety of predictor variables that we hypothesized would influence the magnitude of cost flow to and from different locations (where the cost flow from Region A to B refers to the costs of IAS in Region B that are due to native species from Region A). First, we extracted the number of unique cost references associated with each receiving country in each decade as a proxy for research effort ('Reference_ID' field in the InvaCost database). Second, we summed the total number of species involved in the cost flows between countries for each decade. Third, we summed the total cost, incurred between 1960 and 2020, of IAS originating from each country.

Beyond these InvaCost-specific predictors, we employed several external variables hypothesized to influence the magnitude of cost flows due to biological invasions⁴⁷. We extracted the total volume of imported goods (in metric tonnes) for each country pair from the Centre d'Études Prospectives et d'Informations Internationales' (CEPII) Base pour l'Analyse du Commerce International (BACI) database⁴⁸ for the years 1995-1999 inclusive and 2015-2019 inclusive, selecting the HS92 designation of harmonized import and export records (see Supplementary Table 6 example data from 10 pairs). We calculated the mean annual flow of goods between each country pair for the 1995-1999 period and dubbed this 'historical trade'. Historical trade can be more predictive of present-day invasion risk due to invasion lags (see ref. 47), but we note that consistent import data are not available for the entire period of our cost data. The mean annual flows for 2015-2019 reflect recent trade (before the COVID-19 pandemic). To assess the role of origin and recipient biodiversity in dictating the flow of invasion impacts, we downloaded species richness data for each country from Mongabay, which tallies species richness for amphibian, bird, fish, mammal, reptile and vascular plant species⁴⁹. As a proxy for environmental matching, we identified countries that shared at least one terrestrial biome⁵⁰ using data from Global Administrative Areas v.3.6. We assumed that country pairs sharing terrestrial biome(s) also share some freshwater and marine environments with similar conditions. Note that we also tested the effect of a shared climate zone variable, but the biome model had greater deviance explained. We also used the mean annual GDP and human population of each decade, and surface land area (reported in 2018 and measured in km², including inland waters but excluding marine Exclusive Economic Zones), tourism expenses (in 2022 US\$), tourism receipts (in 2022 US\$), agriculture, fisheries and forestry value added (in 2022 US\$), gross capital formation (in 2022

US\$), road density (km per 100 hectares) and percent of imports relating to food (as a percentage of all imports) from the World Bank using the wbstats R package⁵¹, the latitude of each country from the rworldmaps R package⁵² and the distance between countries variable from the CEPII GeoDist database (calculated between two most populous cities), which has previously been employed to model invasional flows². On the basis of ref. 2, we also extracted information on common language (spoken by at least 9% of the population in each country), the existence of a free-trade agreement between countries, a shared colonial history (CEPII Gravity Database) and shared geographical borders (reported in ref. 2). To test whether cost flows could be predicted from the total number of IAS (with and without costs) that occur in a recipient region, we obtained data on IAS load per country from ref. 32.

Missing predictor variable values were filled in with either the closest decade of available data or the mean of non-missing values when entirely missing (Supplementary Note 6). High levels of multicollinearity among variables led to the removal of GDP and tourism variables (collinear with gross capital formation and research effort) as well as gross capital formation in the receiving country (collinear with research effort) and the total IAS load per country (collinear with tourism, research effort and recipient country area) from our model (all r > 0.70) (ref. 53). We considered human population and economic output instead of human population density and output 'per capita' because the qualifying variables (surface land area for human population and human population for output) were already included in the model. Moreover, ratio variables are well-known to cause spurious effects if there is a correlation between the denominator of the ratio and the response variable⁵⁴. Our approach therefore allows for greater non-linearity and flexibility in considering these independent variables and their partial effects.

Statistical modelling

We built predictive models of the cost flow between each country pair for all complete (non-zero) flows recorded in InvaCost (Fig. 2). To do this, we first summed our cost data within each decade and within each sender-recipient country combination, employing the countrycode R package⁴⁴ to ensure consistent country naming by converting all InvaCost country records to ISO3C codes. All models were fitted as generalized additive models (GAMs) using the mgcv package⁵⁵, where all quantitative predictors and the cost flows (in millions of US\$) were logarithmically scaled. Decade was included as a thin-plate smoother term with five knots (a maximum of four inflection points in its functional form) to de-trend the cost flows for consistent variability in time. This variability could be due, for instance, to periods of global economic growth and decline. The 'numbers of species involved' predictor per cost flow controlled for the expected increase in IAS impacts due to a simple increase in IAS sent or received. Within each GAM, we employed the 'select' method to avoid the overparameterization of our smoother terms. This method uses a cross-validation approach to penalize overfitted smoother terms (using the GCV.Cp method). All non-smoothed variables were log_e-transformed before analysis to meet model assumptions as determined by GAM model-checking results. Models were checked for high concurvity using the mcgv function 'concurvity' (the GAM equivalent of multicollinearity⁵⁵), where 'worst-case' concurvity values of >0.8 were taken to indicate model overfitting. Model residual and quantile-quantile plots were produced to check log-log model goodness-of-fit relative to an untransformed model (Supplementary Figs. 7 and 8). Sensitivity to research effort was further tested by reanalysing the model in terms of cost per publication associated with each pairwise country flow. Sensitivity of parameter relationships to high amounts of data from the USA was tested by adding 10%, 50% and 100% more bootstrapped data rows from non-USA countries. Sensitivity to the assumption that sender costs were spread evenly across native range countries was tested by reweighting costs for species with multicountry native ranges by each native range country's wealth (acknowledging that this is not necessarily any more reflective of true sender dynamics than an equal split).

Reporting summary

Further information on research design is available in the Nature Portfolio Reporting Summary linked to this article.

Data availability

The InvaCost database v.4.1 is available in the form of a publicly available repository at https://doi.org/10.6084/m9.figshare.12668570. All derived data have been archived in Zenodo at https://doi.org/10.5281/zenodo.7778972.

Code availability

All code used for data analysis and producing figures has been archived in Zenodo at https://doi.org/10.5281/zenodo.7778972.

Extended Data Fig. 4 | Decadal cost flows after controlling for research effort. Costs sent and received per decade, qualified by numbers of publications. Base map is public domain, courtesy of Wikimedia Commons.

Extended Data Fig. 5 | Top sender and receiver countries after controlling

for research effort. Top 10 IAS cost sender countries (a), top 10 IAS cost receiver countries (b) and top 10 sender-receiver country pairs (c) in the InvaCost database when total reported costs are qualified by numbers of publications per country. Costs correspond to qualified invasion impacts in 2017 US\$ values of species native to a country across all receiving countries (a), qualified invasion costs per country attributable to individual species native to any other country (b), and qualified invasion costs incurred per receiver country attributable to species native to the corresponding sender country (c). In (c), darker red hues indicate greater senders of costs, darker blue hues indicate greater receivers of costs, and blacker hues represent countries that both receive and send high costs. Countries are not to scale. Arrows indicate species' known native ranges and final recipient regions of costs and therefore do not necessarily indicate direct flows between countries. Extended Data Fig. 6 | **Relative extent of IAS flows compared to trade flows.** Percentiles of the extent of trade plotted on the x-axis (where greater net importers are further to the right) and percentiles of the net flow of IAS costs on the y-axis (where greater net importers of IAS risk are higher up) for each country plotted by ISO3C code. Countries in the top left quadrant have greater net export of goods and greater net import of IAS costs (for example Canada, Australia, and Colombia). Countries in the top right quadrant have greater net import of both goods and IAS costs (for example USA, United Kingdom, Philippines). Countries in the bottom left quadrant have greater net export of both goods and IAS costs (for example Brazil, South Korea, Russia), and countries in the bottom right quadrant have greater net import of goods and net export of IAS costs (for example China, India, Mexico). Country text colour was allocated by continent analogously to Fig. 1.

Reporting Summary

Nature Research wishes to improve the reproducibility of the work that we publish. This form provides structure for consistency and transparency in reporting. For further information on Nature Research policies, see our <u>Editorial Policies</u> and the <u>Editorial Policy Checklist</u>.

Statistics

For all statistical analyses, confirm that the following items are present in the figure legend, table legend, main text, or Methods section.			
n/a	Confirmed		
	\boxtimes	The exact sample size (n) for each experimental group/condition, given as a discrete number and unit of measurement	
\boxtimes		A statement on whether measurements were taken from distinct samples or whether the same sample was measured repeatedly	
	\boxtimes	The statistical test(s) used AND whether they are one- or two-sided Only common tests should be described solely by name; describe more complex techniques in the Methods section.	
	\boxtimes	A description of all covariates tested	
	\boxtimes	A description of any assumptions or corrections, such as tests of normality and adjustment for multiple comparisons	
	\boxtimes	A full description of the statistical parameters including central tendency (e.g. means) or other basic estimates (e.g. regression coefficient) AND variation (e.g. standard deviation) or associated estimates of uncertainty (e.g. confidence intervals)	
\boxtimes		For null hypothesis testing, the test statistic (e.g. <i>F</i> , <i>t</i> , <i>r</i>) with confidence intervals, effect sizes, degrees of freedom and <i>P</i> value noted <i>Give P values as exact values whenever suitable.</i>	
\boxtimes		For Bayesian analysis, information on the choice of priors and Markov chain Monte Carlo settings	
	\boxtimes	For hierarchical and complex designs, identification of the appropriate level for tests and full reporting of outcomes	
\boxtimes		Estimates of effect sizes (e.g. Cohen's d, Pearson's r), indicating how they were calculated	
		Our web collection on statistics for biologists contains articles on many of the points above.	

Software and code

Policy information about <u>availability of computer code</u>

Data collection Origin region information was compiled by co-authors using Microsoft Excel for Mac 2021 and Google Sheets from the Google Docs suite. Web scraping code was written in R version 4.1.0.

Data analysis Analysis was performed in R version 4.1.0.

For manuscripts utilizing custom algorithms or software that are central to the research but not yet described in published literature, software must be made available to editors and reviewers. We strongly encourage code deposition in a community repository (e.g. GitHub). See the Nature Research guidelines for submitting code & software for further information.

Data

Policy information about availability of data

All manuscripts must include a data availability statement. This statement should provide the following information, where applicable:

- Accession codes, unique identifiers, or web links for publicly available datasets
- A list of figures that have associated raw data
- A description of any restrictions on data availability

All code and data are available at https://doi.org/10.5281/zenodo.7778972- mentioned in the data and code availability statements. The raw data for all figures has also been reported in the data availability statement.

Field-specific reporting

Life sciences

Please select the one below that is the best fit for your research. If you are not sure, read the appropriate sections before making your selection.

Ecological, evolutionary & environmental sciences study design

All studies must disclose on these points even when the disclosure is negative.

Study description	To investigate the spatial distribution of senders and receivers of sustainability challenges triggered by invasions, we quantify the monetary burden within and flowing between sender and recipient regions (continents or countries). Specifically, we examine: (i) whether some continents or countries send or receive a disproportionate amount of economically costly IAS, and costs associated with those IAS; and (ii) whether socio-economic and environmental variables predict cost flows between country pairs.		
Research sample	We extracted cost data from the latest version of the InvaCost database (version 4.1, publicly available at 10.6084/ m9.figshare.12668570). For this analysis, we considered costs with impact years between 1960 and 2020, given limited InvaCost data before 1960, and constraints on the availability of relevant socio-economic variables beyond this period (see "Predictor variables" section of methods).		
	We further considered species-specific cost entries only, thus excluding those for diverse (where costs were reported collectively for multiple taxa) or unspecific (where species-level information was missing) taxa. Likewise, we removed costs reported in unspecified geographic regions (those that could not be attributed to any continents or countries) and blank cost entries. We additionally removed cost entries for disease agents (viruses, bacteria, human pathogens) from the data, as these taxa are equivocally identified as non-native, and we are typically more interested in the movement of their vector species. For example, invasive alien mosquitoes (Aedes spp.) would be included, while the viral diseases they vector (yellow fever, zika, chikungunya etc.) would be excluded. We also opted to use the most robust subset of these resulting data, by considering only costs that were of high method reliability (from peer-reviewed literature or other sources with documented, reproducible and traceable methods) and empirically observed (costs actually incurred, rather than expected or predicted). Further, we removed cost entries at the 'unit' spatial scale (belonging to various minor scales below the site level) because of the higher likelihood of double-counting with costs at larger geographic scales, and because the total area over which these costs were incurred was variable and often unreported (for example, costs reported per m^2 without indicating the total size of the area impacted).		
Sampling strategy	Sampling was not relevant as the study did not involve primary data collection		
Data collection	Data from InvaCost were downloaded with the invacost R package 1.1-4 and filtered following the rules mentioned above in "Research Sample". As a first step in determining species' countries of origin, we employed a web scraping script to gather data from the Centre for Agriculture and Bioscience International (CABI) Invasive Species Compendium (ISC, www.cabi.org/isc), the International Union for Conservation of Nature (IUCN) Global Invasive Species Database (GISD, http://www.iucngisd.org/gisd/) and the Global Biodiversity Information Facility (GBIF, www.gbif.org) (see www.github.com/emmajhudgins/Givers_Takers for more information). Our script searched using the species names as entered within InvaCost (harmonized using the GBIF.org Backbone Taxonomy); as well as synonyms in the Integrated Taxonomic Information System (ITIS) database via the taxize R package version 0.9.100. If a species match was found within the CABI ISC, we searched for a "Distribution Table" portion of the species' entry. If found, we extracted country or region (within country) names tagged as "Native" within this table. GISD contains geographical information for many IAS, and was used as an alternative to CABI where distributional data were missing. Our script searched for GISD distributional data points tagged "Native" and compiled them at the country level. Finally, we checked for matching entries in GHF — a global database of all types of species distribution — tagged as "Native" at the country level within the coc_search function of the rgbif package version 1.4.0. All origin assignments were checked manually by co-authors (where we ensured that there existed at least 1 reliable source that agreed on the origin continent at least), or were entered for the first time when information was unavailable from GISD and CABI, using available literature and databases. Literature was identified through ad hoc, informal searches. A list of literature sources used to check the species' origins is provided in Supplementary Note 4.		
Timing and spatial scale	Data from 1960-2020 were used in this study, with variable timing of costs within each study's cost estimates.		
Data exclusions	Beyond the filtering steps described in the research sample step above, no data were excluded.		
Reproducibility	Since no experiments were performed, this section is already covered by our data availability and code availability statements as well as answers to the questions above.		
Randomization	Randomization was not relevant as the study was not experimental		
Blinding Blinding was not relevant as the study was not experimental			
Did the study involve field	d work? Yes X No		

Reporting for specific materials, systems and methods

We require information from authors about some types of materials, experimental systems and methods used in many studies. Here, indicate whether each material, system or method listed is relevant to your study. If you are not sure if a list item applies to your research, read the appropriate section before selecting a response.

Materials & experimental systems

- n/a Involved in the study
- \ge Antibodies
- \boxtimes Eukaryotic cell lines
- \times Palaeontology and archaeology \square
- \boxtimes Animals and other organisms
- \ge Human research participants
- \boxtimes Clinical data
- \boxtimes Dual use research of concern

Methods

- Involved in the study n/a
- \boxtimes ChIP-seq
- \boxtimes Flow cytometry
- \ge MRI-based neuroimaging \square
