How do attention and consciousness interact in the human brain? Rival theories of consciousness disagree on the role of fronto-parietal attentional networks in conscious perception. We recorded neural activity from 727 intracerebral contacts in 13 epileptic patients, while they detected near-threshold targets preceded by attentional cues. Clustering revealed three neural patterns: first, attention-enhanced conscious report accompanied sustained right-hemisphere fronto-temporal activity in networks connected by the superior longitudinal fasciculus (SLF) II-III, and late accumulation of activity (>300 ms post-target) in bilateral dorso-prefrontal and right-hemisphere orbitofrontal cortex (SLF I-III). Second, attentional reorienting affected conscious report through early, sustained activity in a right-hemisphere network (SLF III). Third, conscious report accompanied left-hemisphere dorsolateral-prefrontal activity. Task modeling with recurrent neural networks revealed multiple clusters matching the identified brain clusters, elucidating the causal relationship between clusters in conscious perception of near-threshold targets. Thus, distinct, hemisphere-asymmetric fronto-parietal networks support attentional gain and reorienting in shaping human conscious experience.

How does attention impact consciousness? Decades of research have revealed that attention is composed of a family of neurocognitive processes, including endogenous and exogenous spatial attention, featuring partially distinct behavioral and neural dynamics^{1,2}. However, how these processes interact with consciousness remain unclear^{3–6}. For example, the available evidence suggests that endogenous, or top-down, attention plays little role in supporting conscious perception^{4,6–8}, while exogenous (bottom-up or stimulus-driven) attention is a necessary, although not sufficient, condition for conscious perception^{9,10}.

Rival theories of consciousness vary in the role ascribed to attention in conscious perception, both conceptually and neurally, and especially in the role of fronto-parietal (FP) networks¹¹, which are strongly associated with attention processing^{12,13}. Consequently, the proposed relationship between attention and consciousness is one of the key distinctions between consciousness theories¹⁴. Some theories explicitly include attention as a modulating factor for consciousness, without taking into account the full complexity of attentional processes^{6,15,16}. According to the global neuronal workspace hypothesis, to attain conscious processing near-threshold stimuli must be attended and consequently receive top-down amplification¹⁵. In conscious perception, neural information is sustained and globally broadcasted across the brain, with an important role for dorsolateral prefrontal cortex (PFC) and inferior parietal cortex¹⁷. This idea about the relationship between attention and consciousness is also consistent with the gateway hypothesis¹⁶. In other theories, consciousness depends partly or not at all on attention-associated regions in the frontal or parietal cortex, without an explicit conceptual role for attention. For example, the integrated information theory¹⁸ postulates that conscious information is integrated in a temporo-parietal-occipital hot zone¹⁹, and the recurrent processing theory²⁰ holds that conscious experience emerges from reverberating activity in sensory areas. Both theories postulate that FP networks contribute to post-conscious cognitive processing and task relevance of targets, such as motor planning or verbal report^{21,22}, and claim that attention and consciousness are distinct both conceptually and neurally. Alternatively, attention and consciousness could be implemented by distinct neural mechanisms but have cumulative influence on the behavioral report. The cumulative influence hypothesis postulates the existence of an interaction between attention and consciousness solely at the behavioral level, but not in neural activity⁶.

One reason for this theoretical divergence might be that the exogenous/endogenous distinction is not always taken into account. In neurotypical participants, exogenous cues near the spatial location of an upcoming near-threshold target increase the target's conscious detection^{7,9,23}. This increase is accompanied by a higher activation of the dorsal FP attentional network²⁴ for seen compared to unseen targets at attended locations²⁵. Moreover, neurological patients with signs of spatial neglect²⁶ display a systematic pattern of association between right-biased exogenous attention and unawareness of left-sided events²⁷. This clinical evidence strongly suggests a specific role for right hemisphere FP attention networks in conscious processing.

Despite this converging evidence, which points to the modulation of consciousness by exogenous attention in both behavior and neural activity, it is still unclear where this interaction occurs in the brain and how different brain networks interact to achieve this effect. Further, the spatiotemporal resolution of neuroimaging techniques like fMRI and EEG used so far to study these questions is too rough for establishing the neural basis of the rapid and dynamic exogenous attention modulation of conscious perception. Facing the divergence of theoretical predictions, and

the resolution limitations of the evidence collected hitherto, we decided to use a data-driven approach to try to establish the dynamics of the neural interactions between attention and consciousness on a fine scale, by taking advantage of the excellent spatiotemporal resolution of human intracerebral EEG (iEEG) recordings. Using unsupervised clustering, we tested empirically the division of functional clusters of iEEG contact based on the neural temporal patterns of the interaction between exogenous attention and conscious report (here, broadly defined as a set of processes leading to conscious access and consequent report), which was experimentally manipulated in a subjective conscious report task. This allowed us to reveal the brain areas supporting different patterns of interactions between attention and consciousness. We further employed white-matter tractography to collect connectomic evidence on the network architecture of the functional clusters. Finally, we used recurrent neural network models to causally examine the computations in the neural clusters and elucidate inter-cluster interactions, which critically contribute to behavior.

Results

Behavioral results: cue validity modulates target detection. We recorded neural activity from 727 intracerebral contacts in 13 patients receiving presurgical evaluation of drug-resistant epilepsy (age 34.7 ± 8.7 years; 7 women). Patients performed a near-threshold target detection task²⁸ (Fig. 1a), in which they attempted to detect left- or right-tilted, near-threshold Gabor patches (the targets), presented either left or right of fixation. The target was preceded by supra-threshold peripheral non predictive visual cues, which appeared either on the same side as the subsequent target (Valid cues) or on the opposite side (Invalid cues). All conditions (target side, cue validity) were randomly interleaved, with 20% of cue-only, catch trials, where no target was presented. Individual Gabor contrasts based on an individual calibration procedure were used across all conditions. Participants had to discriminate the direction of the Gabor's tilting, and subsequently report the presence or absence of the Gabors. They were informed that cues did not predict the location of the upcoming targets.

To see whether exogenous attention modulates the conscious perception of targets in the discrimination task, we performed a two-way ANOVA with the factors of cue validity and conscious report on the percentage of accurate responses. As expected, participants were more accurate in discriminating target direction when the targets were reported to be perceived than when they went unseen (main conscious report effect: $F_{1,24} = 24.74$, $p < 0.001$, $\eta^2 = 0.315$). Although the main validity effect did not reach significance ($F_{1,24} = 1.04$, $p = 0.31$, $\eta^2 = 0.013$), validity interacted with conscious detection, because validly cued targets were more likely to be reported than invalidly cued ones ($F_{1,24} = 4.77$, $p < 0.05$, $\eta^2 = 0.061$, see Fig. 1b; post hoc *t*-test: valid vs. invalid for seen targets, two-sided, degree of freedom = 12, *t* value = 3.04, $p < 0.05$, Cohen's $d = 0.84$). Signal detection theory (SDT) analysis showed that on target-present trials valid cues induced a higher detection rate (more seen targets; pairwise *t*-test, $p < 0.05$, Cohen's $d = 0.58$), and a more liberal response criterion (pairwise *t*-test, $p < 0.01$, Cohen's $d = 1.03$) than invalid cues did (Supplementary Fig. 1a). On catch trials where no target was presented, participants (erroneously) reported more targets as occurring on the cued side than on the uncued side (pairwise *t*-test, $p < 0.01$, Cohen's $d = 0.87$). However, no significant difference emerged in sensitivity (pairwise *t*-test, $p = 0.52$). No significant interaction effects were found in response times.

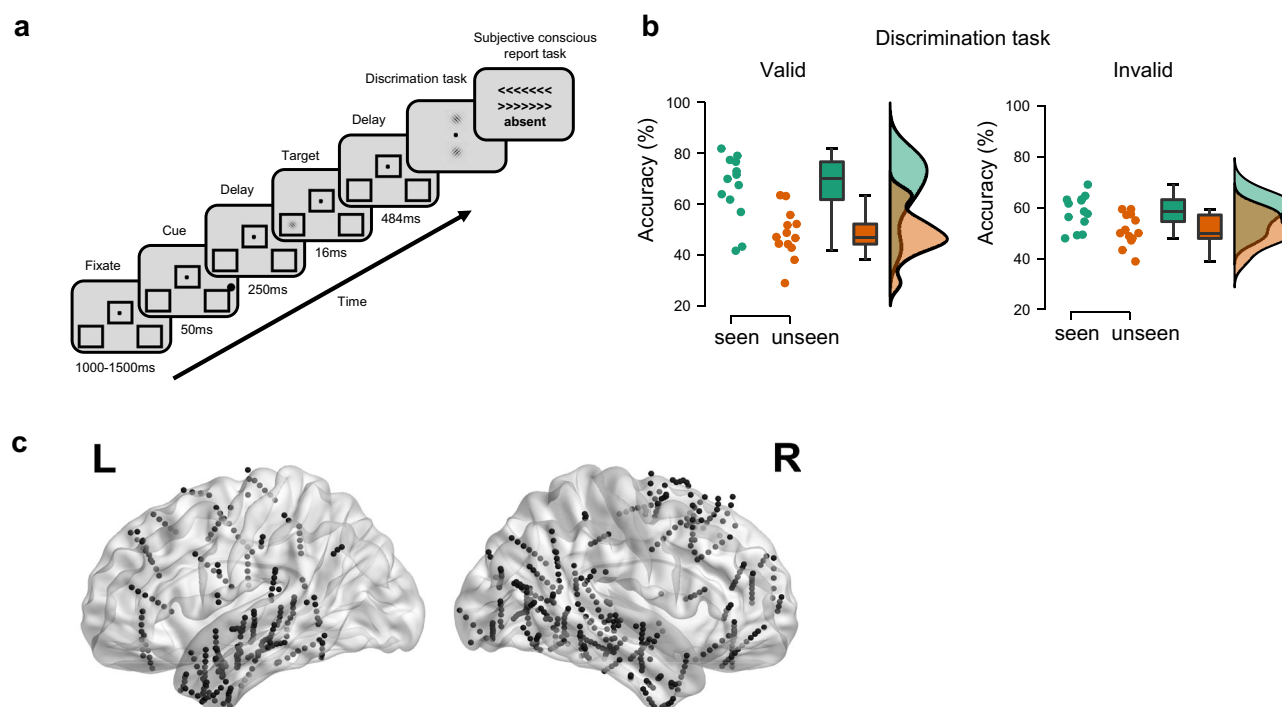

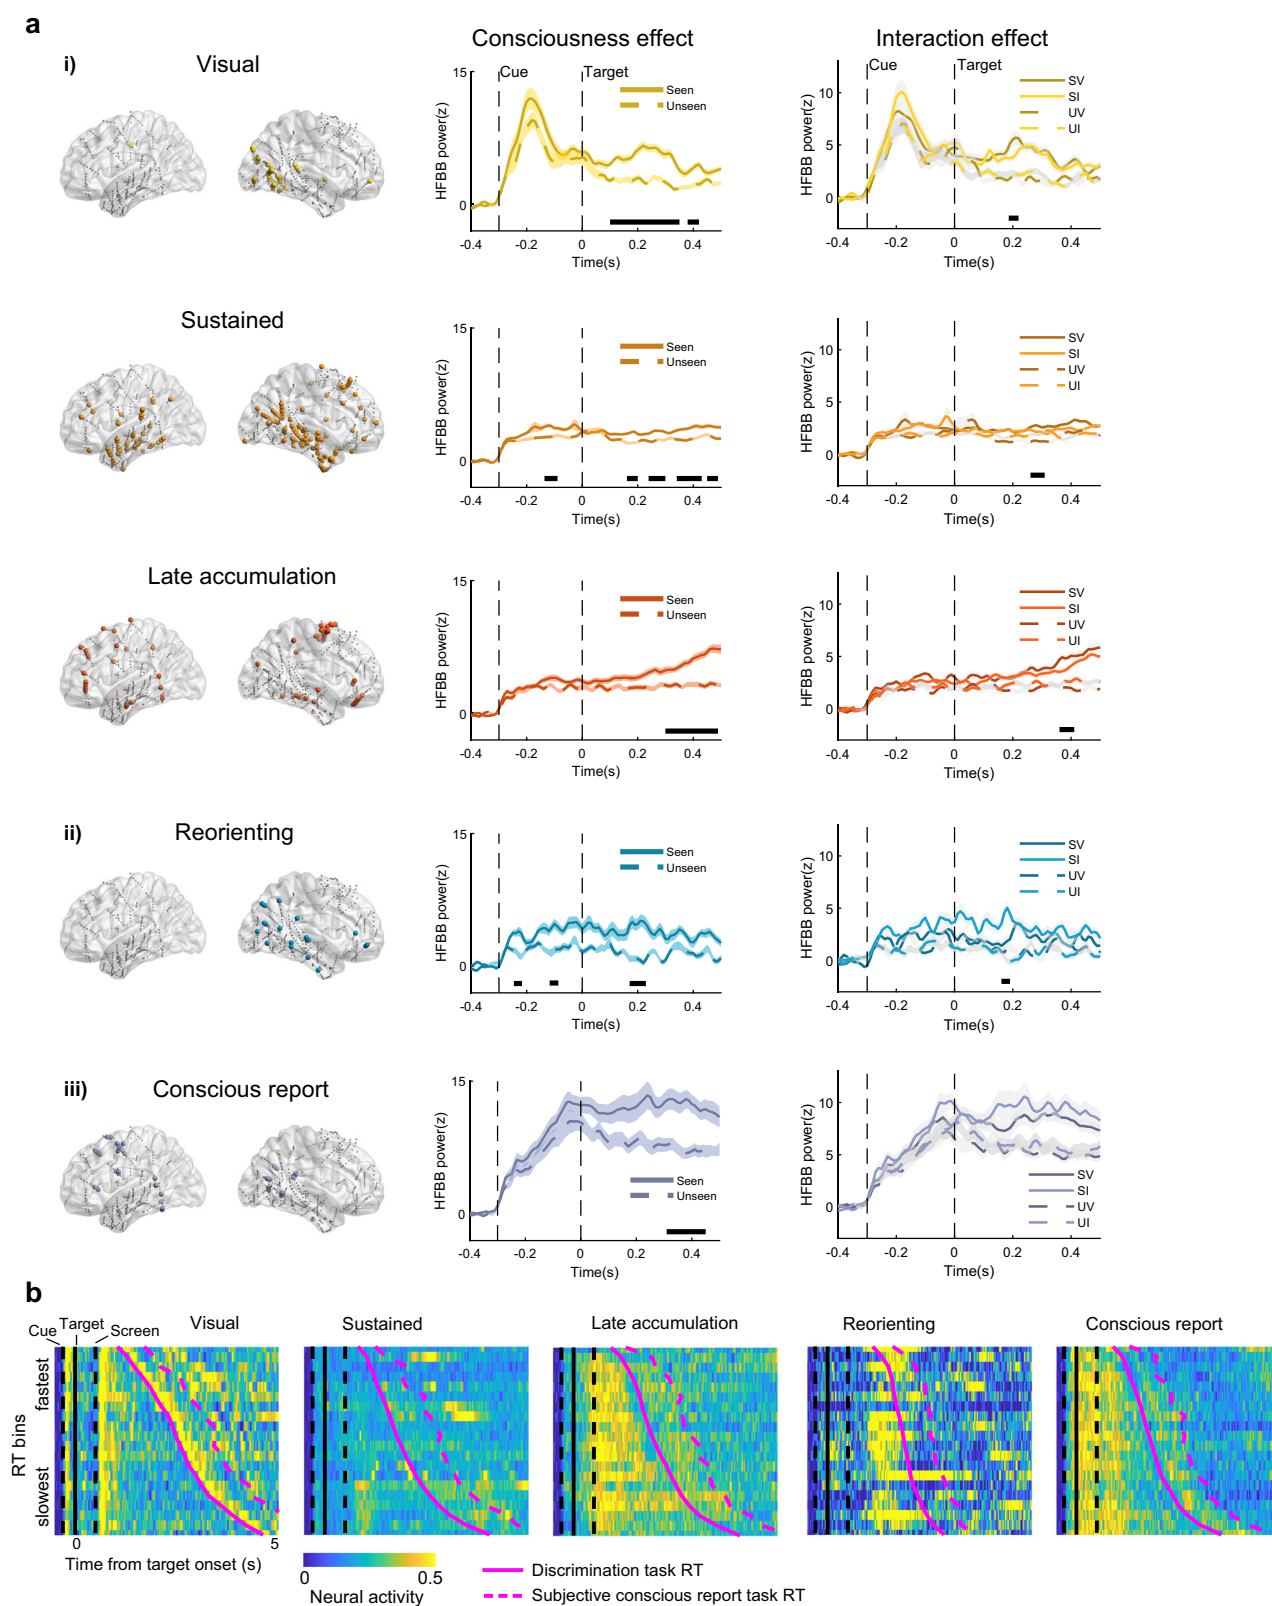

Fig. 1 Near-threshold target detection task and human intracerebral recordings. **a** After a fixation dot lasting 1000–1500 ms, a peripheral non-predictive dot cue occurred for 50 ms, followed by a left-sided or right-sided near-threshold tilted Gabor target presented for 16 ms. After a delay of 484 ms, participants discriminated the direction of tilting and reported the presence or absence of the Gabor. In 20% of trials (catch trials), the Gabor target was absent. Individual contrasts based on an individual calibration procedure were used across all conditions. **b** Discrimination task. Dots represent individual performance. Chance level is at 50%. Boxplot shows values of median, upper quartile, lower quartile, maximum and minimum, respectively. **c** The 727 intracerebral contacts pooled from 13 epileptic patients in MNI space, see detailed localization label in Supplementary Table 1. The black dots show contacts on the lateral cortical surface and the gray dots for deeper contacts.

Five neural clusters associated with consciously perceived targets form three patterns of interaction with attention. After discarding epileptic artifacts, there were 727 usable contacts with bipolar montage pooled across all participants (288 in the left hemisphere; 439 in the right hemisphere; Fig. 1c, see Supplementary Table 1 for details). For each contact, we extracted high-frequency broadband power (HFBB; 70–140 Hz), which is generally considered as a proxy of neuronal population activity^{29,30}, but also see ref. ³¹. We then computed target-locked mean normalized HFBB across the eight experimental conditions ($2 \times 2 \times 2$ design: target side [ipsilateral/contralateral] \times cue validity [valid/invalid] \times conscious report [seen/unseen]). Neural activity components of all contacts were visualized in a two-dimensional t-distributed stochastic neighbor embedding (t-SNE) (Supplementary Fig. 1b).

Next, we applied a trajectory *k*-means clustering method³² to identify the main groups of contacts that carry cue validity and conscious report information (see Methods). This procedure allowed us to group intracerebral contacts based on their temporal profile of neural activities across the experimental conditions. For each contact, we computed the temporal trajectory in the eight-dimensional condition space, i.e., the path of each contact's HFBB power over time across all conditions (target side, cue validity, conscious report). Using *k*-means clustering, each trajectory was then assigned to the cluster with the nearest trajectory-centroid, by iteratively minimizing within-cluster Manhattan distances. A ten clusters solution reflected the highest average silhouette score serving as the evaluation criterion of the clustering results (Supplementary Fig. 2a). We explored how our experimental manipulation of attention and consciousness influenced the clusters' activity. For each cluster, we performed time-resolved 3-way ANOVAs in both the cue-target

period (from -300 ms to target onset) and the post-target period (from target onset to 500 ms post-target) with the factors of target side, validity, and conscious report. Five of the ten clusters showed a main effect of conscious report, with higher levels of activity for seen than for unseen targets (all p s < 0.018). The number of contacts in these clusters was stable (Supplementary Fig. 2d) and their cluster-level temporal profiles were similar across *k*-means solutions with varying numbers of clusters. We thus focused on these clusters for further analyses (see Supplementary Table 1 for details about anatomical localization in each cluster). The remaining five clusters didn't show any significant effects and were not included in further analysis. We then explored how exogenous attention affects conscious reports of the targets in the five clusters, by examining the interaction between Cue validity and Conscious report (valid/invalid \times seen/unseen) in the above mentioned time-resolved ANOVA. This analysis revealed 3 distinct patterns of neural activity. We will describe the interaction patterns as well as the main effect of conscious report in the cue-target and post-target periods for the five clusters (Fig. 2a).

First, the first interaction pattern encompassed three out of the five clusters and showed enhanced conscious report neural effect for validly cued targets compared to invalidly cued targets: the first cluster (42 contacts) showed an early transient post-target effect, with stronger activation for seen targets compared to unseen ones (90–350 ms and 380–430 ms, all p s < 0.003 ; hereafter: the Visual cluster). Additionally, the Visual cluster showed an interaction between target side and cue validity in the cue-target period (60–210 ms after cue onset, all p s < 0.006 , Fig. S2E), with higher neural activity for contralateral than for ipsilateral cues. However, there was no significant Target side effect in the post-target period, perhaps because of the low, near-threshold intensity

of the targets. No significant three-way interaction emerged (all $F_s < 8.17$, $p_s > 0.20$). This cluster mainly consisted of contacts in the right posterior temporoparietal areas (there was no available electrode in the homolog areas of the left hemisphere). To test whether the cue-dependent potentiation of baseline in the cueing period leads to subsequent increased target perception, we compared the activity associated with seen and unseen targets

in the hemisphere contralateral to the cue, before target occurrence. We observed that the cues which preceded conscious target reports elicited higher neural activation in the Visual cluster (-150 to -100 ms before target onset, all $p_s < 0.045$, Supplementary Fig. 2f); in the second cluster (148 contacts), the conscious report effect was present both in early cue-elicited (-140 to -90 ms before target onset, all $p_s < 0.016$, see also

Fig. 2 Trajectory k-means clustering revealed five clusters showing a conscious report effect and three patterns of interaction of exogenous attention with conscious report. **a** Three neural patterns of the validity \times conscious report interaction: i) three clusters (Visual, Sustained, Late accumulation) showed enhanced conscious report effect for the validly cued targets. For each cluster, the figure shows: cluster contact localization; comparison of target-locked neural activity for seen and unseen trials; comparison of interaction effect, SV: seen valid; SI: seen invalid; UV: unseen valid; UI: unseen invalid. Black horizontal bar for all $ps < 0.05$, Holm-Bonferroni corrected, gray shading is \pm SEM across electrodes. ii) Reorienting cluster showed early sustained neural activity for invalidly cued targets. iii) a late Conscious report cluster differentiated seen from unseen targets independent of attention. Note that the Sustained cluster and the Reorienting cluster also showed significant conscious target report effects during the cueing period, before target occurrence. **b** Visual- and RT-modulation of target-locked neural activity. RT bins were sorted according to their mean RT from fastest to slowest, with neural activity pooled across contacts in each cluster. Magenta full curve shows mean discrimination task RT, followed by dashed magenta curve for mean subjective conscious report task RT. Neural activity in the Visual cluster synchronized with visual stimuli (cue, response screen and screen switching after discrimination task). Late accumulation cluster showed sustained neural activity until the response. Conscious report cluster exhibited sustained neural activity locked to the visual percept, but not to the report.

Fig. S2F) and in later, target-related sustained neural activity (160–200 ms, 240–300 ms, 340–430 ms, and 450–500 ms post target, all $ps < 0.003$; hereafter, Sustained cluster). The contacts of the Sustained cluster were mainly located in the bilateral temporal cortex, the right angular gyrus, and the right PFC, around the central portion of the right superior frontal gyrus; the activity of the third cluster (67 contacts) slowly increased with over time build-up in the post-target period for seen targets (300–500 ms, all $ps < 0.005$; hereafter, Late accumulation cluster), but there was no significant conscious report effect in the cue-target period. Most of the contacts in the Late accumulation cluster were located in the bilateral PFC, around the left inferior frontal gyrus (IFG), the right orbitofrontal cortex and the caudal portion of the right superior frontal gyrus. Similar to the attentional enhancement on conscious report in behavior, there was an attention-related enhancement interaction with conscious report in the three neural clusters (Visual cluster: 190–220 ms, all $ps < 0.03$; Sustained cluster: 270–330 ms, all $ps < 0.002$; Late accumulation cluster: 360–430 ms, all $ps < 0.006$). The amplitude of this interaction did not significantly differ across the three clusters by direct comparison (three-way ANOVA with the factors of cluster \times validity \times conscious report, all $ps > 0.30$), possibly due to faint target contrasts. A further explorative analysis compared this enhancement, by using Cohen's d values which were derived from time-resolved t -test for the interaction contrast (seen valid – unseen valid) – (seen invalid – unseen invalid), around the time points where the interaction was significant. The result showed an increasing effect size gradient from the Visual cluster to the Sustained and Late accumulation clusters (Supplementary Fig. 3d, one-way ANOVA: $F_{2,42} = 3.83$, $ps < 0.05$, $\eta^2 = 0.15$, linear polynomial contrast, $p < 0.05$, $t = 2.48$), suggesting an increasing attention modulation on conscious report along these clusters.

Second, another neural cluster (19 contacts) showed a reversed pattern when attention was reoriented from invalidly cued locations to the target, with higher activity for seen targets after invalid cues than for seen targets after valid cues, early after target onset (160–190 ms, all $ps < 0.002$; hereafter, Reorienting cluster). This cluster presented fast activity in the cue-target period (–250 to –220 ms and –130 to –90 ms before target onset, all $ps < 0.015$), as well as early in the post-target period (170–230 ms, all $ps < 0.001$), that resulted in seen reports for uncued targets. This cluster was localized in the right hemisphere temporoparietal junction (TPJ)/IFG. Activity in this cluster was sustained after target onset, then showed a transient peak around 180 ms only for invalid seen targets; however, for seen targets after valid cues, activity decreased once targets appeared. This cluster thus was likely to reflect reorienting of attention from the invalid cue to the opposite target²⁴.

Third, the last neural cluster (38 contacts) showed a late sustained neural activity selective for reported targets (310–450 ms, all $ps < 0.018$), independent of cue validity

(hereafter, Conscious report cluster). This cluster contains contacts from the left posterior portion of dorsolateral PFC, around the left frontal eye field, and the bilateral posterior temporal area.

The differences of temporal components of the three neural patterns in the interaction between exogenous attention and consciousness can be visualized in a two-dimensional t-SNE decomposition (see Supplementary Fig. 3a). This visualization corroborates the separation of neural dynamics of the five clusters in the interaction between attention and conscious report.

We then sought to understand the functional roles of the clusters by relating the neural activities to the behavioral responses. In each cluster, we divided the trials (pooled across conditions) into 20 quantiles according to their response time (RT) in the discrimination task (see Methods; note that in the discrimination task patients had to wait for the onset of a response screen in order to respond). We tested the relation of the neural activities in RT-bins using time-resolved one-way repeated measures ANOVA, in a time window from target onset to 1000 ms, to avoid the influence of neural activity in the subsequent trial. The Late accumulation cluster showed target-locked sustained neural activity in trials evoking slower RTs (340–1000 ms, all $ps < 0.003$; see Supplementary Fig. 3b), but not in trials with faster RTs. The other clusters had no or only transient (less than 300 ms) RT effects for targets. We then compared the neural activity of the ten fastest RT bins with those of the ten slowest RT bins. The Late accumulation cluster showed greater accumulating and sustained activity for slower RTs responses than faster ones (Supplementary Fig. 3c). Interestingly, the Visual cluster showed a stimulus-locked higher neural activity for faster RTs, perhaps because faster responses resulted from stronger evidence for target presence. No significant effect emerged in other clusters. Next, we visualized the neural activity across RT bins over a longer time window, which contains the neural information until the button press (target onset to 5000 ms, see Fig. 2b). Here, activity might be affected by the subsequent trial; hence, we report only observational findings without statistical testing. We observed that the transient response elicited in the Visual cluster was locked to visual modulations (i.e., the appearance of cue, target, screen, and switching of the display after the discrimination task). The Late accumulation cluster showed accumulated and sustained activity until report. The Reorienting cluster shows a late transient response. The Conscious report cluster elicited sustained neural activity, which was locked to the visual percept and was not associated with the time of report. To test whether these activities were related to motor preparation, we computed the beta band power (16–28 Hz), which typically decreases with motor planning³³. There was no sign of decreasing beta activity in the Late accumulation cluster and in the Conscious report cluster. This

Fig. 3 FP white matter tracts connecting contacts in the right hemisphere. Tractography t-maps, showing the significant white matter voxels (threshold-free cluster enhancement-based non-parametric t -test, $p < 0.05$), which connect frontal and parietal contacts within each cluster.

result suggests that motor preparation had little role in eliciting these clusters (Supplementary Fig. 3e).

Fronto-parietal white matter tracts connecting contacts in the right hemisphere. To specify the anatomical connections between contacts within each cluster, we performed white matter tractography analysis paired with probability maps in 176 healthy individuals from the Human Connectome database³⁴. Figure 3 displays the white matter tracts connecting frontal contacts and parietal contacts within each cluster. This result suggests that our unsupervised cluster analysis mapped on existing anatomo-functional networks¹². We examined the frontal association tracts described in ref. ³⁵, and found that our frontal and parietal contacts were connected by branches of the superior longitudinal fasciculus (threshold-free cluster enhancement-based nonparametric t -test, $p < 0.05$). Specifically, the Sustained cluster was mainly connected by the right superior longitudinal fasciculus (SLF) II (43.4%) and III (36.8%). The Late accumulation cluster was mainly linked by the right SLF I (39.4%) and III (25.1%). The Reorienting cluster was connected by right SLF III (84.2%). No statistically significant tracts emerged from the analysis of the Visual and the Conscious report cluster.

Task modeling with recurrent neural network. To better understand the relation between activity dynamics and behavior, we simulated the task with a recurrent neural network (RNN) model (Fig. 4a). We separately modeled left- and right-sided visual stimuli as two noisy signal inputs. The model had a single layer containing 50 units recurrently connected to one another, of which 80% were excitatory units and 20% were inhibitory units. The network was trained by back-propagation to produce two different outputs, one for each side, about the presence or absence of the target. Similarly to the human task, two RNN outputs were combined to measure a discrimination and a detection performance. The task conditions were also similar to the human task, and included valid trials, invalid trials, and 20% catch trials (see examples of stimuli inputs, hidden units dynamic and network outputs in Fig. 4b for valid trial and in Supplementary Fig. 4a for invalid and catch trial).

The trained model displayed a detection psychometric curve, resembling typical human performance^{33,36,37}. This curve differed from that characterizing an untrained model with random Gaussian connectivity weights (all $ps < 0.001$ for stimulus contrast above 0.03, see Fig. 4c). Further, in the trained model, the improvement of target discrimination and detection with valid cues emerged only at sufficiently high stimulus contrast levels (Fig. 4c). Consistent with this task performance pattern, a t-SNE visualization of RNN units' components showed a difference for valid vs. invalid trials only in intermediate or higher target contrasts, but not with lower contrast levels (Supplementary Fig. 4b,c). Thus, all further analyses on RNN units were performed on the intermediate target contrast levels, corresponding to near-threshold targets in the human task.

To identify the temporal patterns of activity of the RNN hidden units, we used our trajectory k -means clustering method. Similar to the human results, the clustering analysis with silhouette evaluation resulted in five stable clusters (Supplementary Fig. 4d) with different temporal trajectories. Four of these clusters showed stronger unit activity for seen targets than for unseen targets (Fig. 4d). Again similar to the human neural data, after an early, transient activity in a Visual cluster (8 units, 110–300 ms, all $ps < 0.017$), there was sustained unit activity in a Sustained cluster (20 units, 140–750 ms, all $ps < 0.032$), and late activity in a Late accumulation cluster (8 units, 300–730 ms, all $ps < 0.038$). Mirroring the model's task performance, the higher the target contrast, the greater the activity in these clusters. Importantly, these clusters showed significantly enhanced activities for validly cued targets at sufficiently high stimulus contrast (Fig. 4e), akin to neural amplification. The fourth, Reorienting, cluster showed early transient activity related to conscious detection (11 units, 170–230 ms, all $ps < 0.019$). A t-SNE visualization of unit activity of these clusters showed distinct unit component patterns for seen targets preceded by valid vs. invalid cues (Supplementary Fig. 5).

To examine potential similarities between RNN clusters and human neural clusters, we used a temporal trajectory correlation analysis. RNN unit activity in the Sustained, Late accumulation, and Reorienting clusters in the trained model were significantly more similar to the equivalent human neural clusters than to the clusters obtained from the untrained model (Fig. 4f, one-sided permutation test, all $ps < 0.001$). We examined how these model clusters are interconnected, and the nature of their computation. In the trained model, we extracted input weights (sensory enhancement gain), connection weights between units, and output weights (report gain) (Supplementary Fig. 4e). The model only constrained the total number of excitatory (E) and inhibitory (I) units. After RNN training, both excitatory and inhibitory units emerged in each cluster. After grouping separately excitatory and inhibitory units in each of the three clusters (a total of six groups), we computed a directed cluster connection graph by averaging unit-to-unit connection weights from one group (pre-synaptic) to each of the other groups (post-synaptic) and compared the resulting connections to random weights (Fig. 4g, one-sample t -test, all $ps < 0.05$, Holm-Bonferroni corrected). The stimuli input was mainly connected to the excitatory units in the Sustained cluster, which was associated with the conscious processing-Sustained intracerebral cluster. The Late accumulation excitatory units were connected to the decision output, confirming its role in decision making. Notably, the Reorienting excitatory units also received a branch of stimuli input and showed strong excitatory connection to the inhibitory units in the Sustained and in the Late accumulation clusters, reflecting the Reorienting cluster's role in early target monitoring and in executing inhibitory control over stimuli processing and decision making units.

Finally, we lesioned each of the RNN clusters to assess their causal contribution to task performance. For each cluster, we

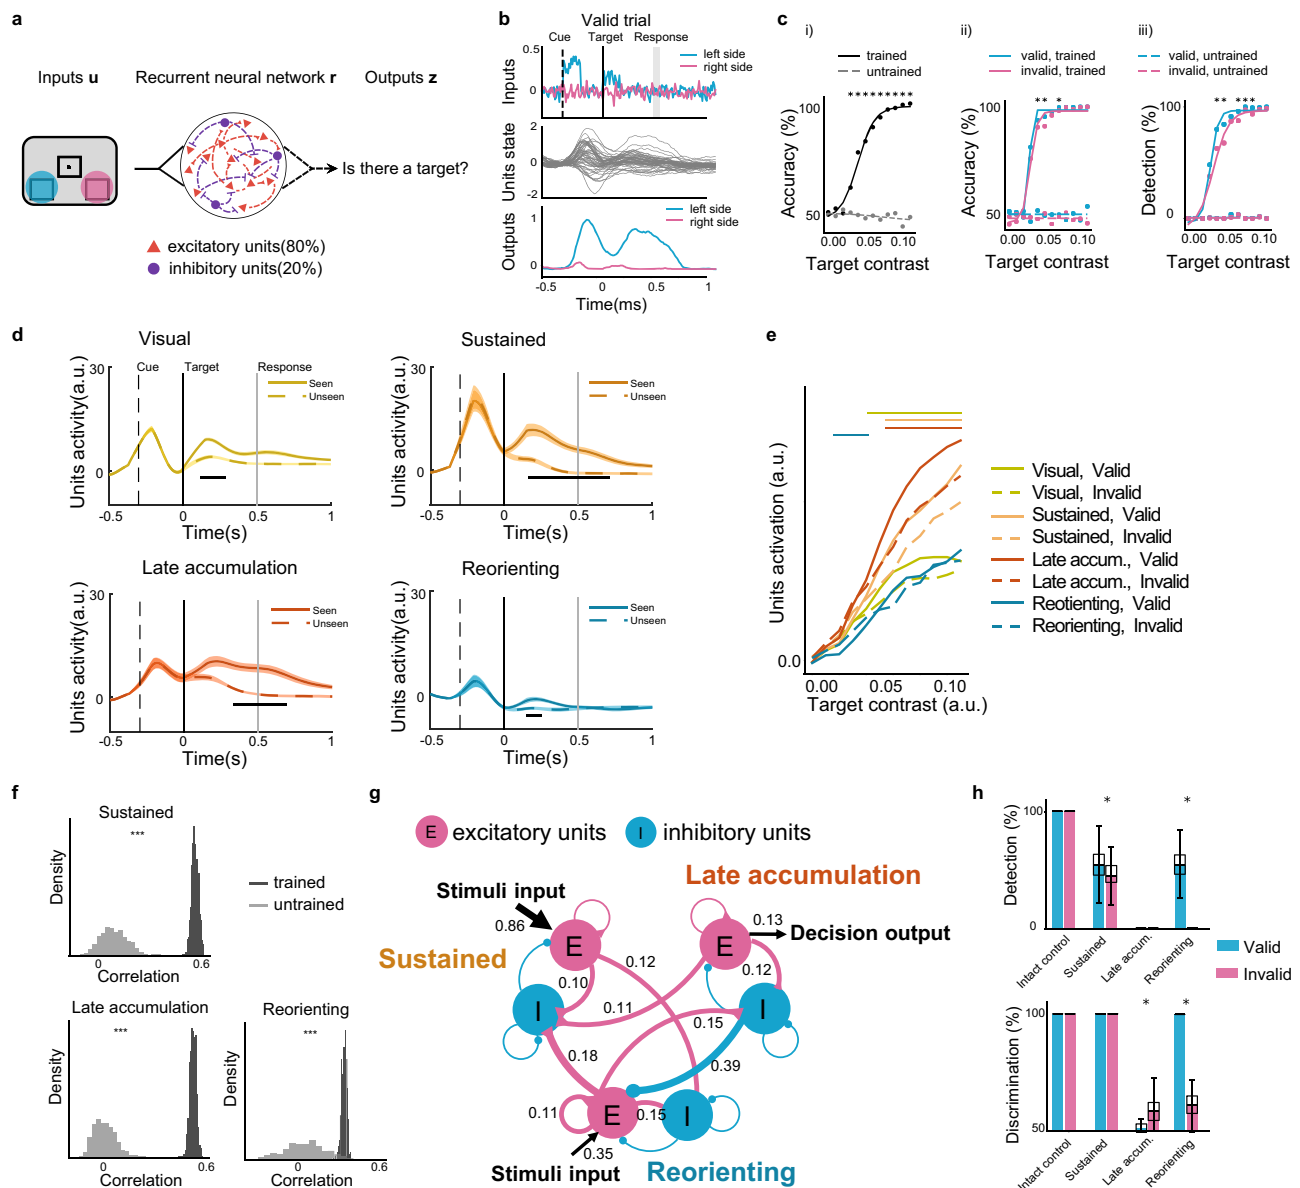

Fig. 4 Task modeling with recurrent neural networks. **a** Recurrent neural network model and task. Left- and right-sided visual stimuli were separately modeled as two noisy inputs. The model had a single layer containing 50 recurrent units. The network produced two outputs to decide whether a target was present on the left or on the right side. **b** Example of a trial showing the task structure and hidden unit dynamic as well as outputs from a trained model. After a fixation period, cue signal was presented on either the left or the right side, followed by a target signal presented on either side or absent. In a valid trial, cue signal and target signal were presented on the same side. Gray vertical line indicates the response window. **c** Task performance. i) discrimination psychometric curve for all targets (validly-cued targets, invalidly-cued targets and target-absent catch trials). Lines show the best-fitting logistic function to 12 target contrasts. ii) comparison of accuracy of the trained model to the untrained model by *t*-test, $*p < 0.001$, Bonferroni-corrected; discrimination psychometric curve. iii) comparison of discrimination accuracy for validly cued targets versus invalidly cued targets in trained model by *t*-test, $*p < 0.05$, Bonferroni-corrected; and detection psychometric curve for validly cued targets versus invalidly cued targets. **d** Trajectory *k*-means clustering of model unit activities. Four unit clusters showed distinct temporal trajectories in seen versus unseen trials for intermediate target contrast level. Black lines for all $*p < 0.05$, Holm-Bonferroni corrected, shading is \pm SEM across electrodes. a.u.: arbitrary unit. **e** Comparison of unit activities for valid versus invalid trials in each cluster while increasing stimulus contrast. Late accum.: Late accumulation. Horizontal bar above the curves for all $*p < 0.05$, Holm-Bonferroni corrected. a.u.: arbitrary unit. **f** Histograms of the correlation coefficient between the trajectory of neural activity and unit activity. Permutation tests, $***p < 0.001$ for trained model versus untrained model. **g** Directed cluster connection graph for groups of excitatory and inhibitory units from three clusters. Magenta curves show excitatory connection and blue curves for inhibitory connection. Triangle or circle at the end of the connection line represents the destination. Numbers denote the weight of connection, with significance level controlled at $p < 0.05$ in one-sample *t*-test, Holm-Sidak corrected across groups of units. **h** Effect of cluster's lesions for detection rate and discrimination accuracy. Intact control: unlesioned model; Late accum.: Late accumulation; Reorienting: $*p < 0.05$ for the comparison of valid versus invalid trials by *t*-test. Boxplot shows values of median, upper quartile, lower quartile, maximum and minimum, respectively.

set all the unit weights to zero, and monitored the change in task performance (Fig. 4h). Lesion of either the RNN Sustained cluster or the Late accumulation cluster decreased the percentage of detected targets (report units). Lesion of the Late accumulation cluster additionally impaired discrimination accuracy. Lesion of the Reorienting cluster led to a selective failure to detect and to discriminate invalidly cued targets (reorienting units). However, performance reverted to normal with very high target contrast levels, presumably because these contrast levels were sufficient to capture attention even without the contribution of the Reorienting cluster.

Discussion

We combined human intracerebral EEG, white matter tractography, and computational modeling to elucidate the fine-scale spatiotemporal dynamics of brain networks underlying exogenous attention modulation of conscious report. Unsupervised temporal clustering revealed three patterns of neural activity in fronto-parietal networks, partially diverging from the classical model of dorsal and ventral attentional networks²⁴. The three neural patterns supported the interaction between exogenous orienting and conscious report: (1) a Sustained cluster showed attention-enhanced sustained activity for validly cued targets; (2) a Late accumulation cluster with progressively showed increasing activity until report; (3) a Reorienting cluster showed an early, sustained response to invalidly cued targets. Using RNN modeling, we discovered multiple clusters matching the identified neural clusters, clarifying the nature of inter-cluster interactions and uncovered the causal contribution of these clusters to behavior. Altogether, our behavioral, neural, and modeling findings consistently demonstrate that exogenous attention, the process that makes external salient stimuli stand out in a visual scene, modulates conscious report.

We demonstrated distinct neural dynamic patterns that implemented signal enhancement and attentional reorienting interacting with conscious report in three right-hemisphere FP networks connected by branches of SLF, as well as inter-network interactions.

At the behavioral level, despite no significant difference in sensitivity between valid and invalid conditions, valid cues increased both discrimination accuracy and detection rate of near-threshold peripheral target and shifted the criterion toward the liberal side, in line with previous findings^{7,10,23,38}. Importantly, the discrimination task, which served as an objective measure of performance, was performed first, closer to the cue and target presentation, and thus the attentional benefits (increased discrimination) were expected to be more readily observable in it. The subjective conscious report task was performed later, after an additional delay, and therefore the cueing benefits (increased *a'* sensitivity) might have been masked by cognitive and motor processes related to the preceding discrimination task (e.g., memory, decision making, action planning). Therefore, attentional benefits are expected to be observed more in the discrimination task than in the subjective reporting (detection) task. Our results are consistent with this prediction: an attention/consciousness interaction benefit was observed in the discrimination task (better discrimination for valid than invalid in seen versus unseen trials), demonstrating the effectiveness of cues in attracting participants' attention.

Dovetailing this attentional enhancement of conscious report effect in behavior, we identified three neural clusters in which validly cued seen targets elicited stronger neural activity than invalidly cued ones. This enhancement occurred first in high-level visual areas as a fast transient target-related activity, then in FP and temporal regions showing a sustained activity, and finally in

bilateral PFC, presenting late accumulation activity, which lasted until the motor response.

Previous evidence showed that attention modulates neural responses across the visual cortical hierarchy, with an increasing magnitude from early to higher-level visual areas^{39,40}. The present findings add to this evidence by indicating the neural location of the effects of attention on conscious report in the visual cortex. Our results clarified that spatial cuing potentiated report-related activity in high-level visual areas (Visual cluster; fusiform gyrus, middle temporal gyrus, inferior temporal gyrus and inferior parietal cortex), but not in the early visual areas.

The Sustained cluster included hotspots around the right superior frontal gyrus and inferior parietal lobule, which were connected by the SLF II network. The attentional enhancement of conscious perception in this cluster may reflect recurrent neural activity which provides a specific neural substrate for neural amplification as suggested by the global neuronal workspace hypothesis¹⁵. The involvement of the SLF II in the attentional modulation of conscious perception is in line with previous clinical evidence showing that damage to the right SLF II is the best anatomical predictor of the occurrence of neglect signs in stroke patients^{26,41}. Importantly, transitory electrical inactivation of the SLF II in the human right hemisphere in a patient undergoing brain surgery provoked severe, if transient, rightward shifts in line bisection, akin to signs of left spatial neglect⁴². The present evidence specifies the temporal dynamics of the right hemisphere SLF II network, by demonstrating its role in attentional amplification of future targets.

Importantly, our findings suggest that the SLF II network, together with high-level visual cortex, support conscious reporting by modeling early cue-related baseline activity. Such activity is likely to improve perception of the subsequent target, in line with a wealth of previous research^{43–45}.

The Late accumulation cluster included focal contacts around the right mesio-frontal and supplementary motor areas connected by SLF I-III network. This cluster showed a late accumulation activity until report, which was enhanced by spatial cuing. This interaction is consistent with its known role of SLF I network in evidence integration and decision making⁴⁶. Alternatively, the activity of this cluster might reflect temporal expectancy for conscious report of targets^{47,48}. In line with early EEG studies⁴⁹, our results demonstrate that attention could enhance conscious expectancy through this FP network.

A reversed pattern of interaction between attention and conscious report occurred when targets appeared at the uncued location: when reported, these targets elicited early, sustained activity in the right hemisphere TPJ and IFG (reorienting network)⁵⁰, connected by the SLF III. The activity of this Reorienting cluster supports the role of the SLF III network in the conscious perception of targets preceded by an invalid cue at the wrong location. Previous neuroimaging evidence has shown the implication of this network in reorienting attention from the invalidly cued location to the targets occurring on the opposite side²⁴. Importantly, our time-resolved results specify that this activity happens earlier than previously thought, before target presentation. This early activity (pre-target until around 150 ms post-target) suggests an anticipatory (lookout) activity for unexpected events such as invalidly cued targets and if necessary, it reorients attention before the attentional enhancement implemented by the SLF II network. Consistent with this hypothesis, early SLF III network activity decreased when the reported targets appeared at the validly cued location.

Finally, independent of attention, seen, but not unseen, targets elicited late sustained activity in the Conscious report cluster located around the posterior portion of left dorsolateral PFC. We ascribed the function of this cluster as likely related to the set of

processes associated with conscious access and the subsequent report. In line with previous neuroimaging evidence⁵¹, this neural activity might reflect the integration of sensory evidence and the formation of decision variables in post-orienting processes that are closely associated with conscious access mechanisms. Another possibility is that the left dorsolateral PFC biases perceptual decisions in conditions of uncertainty⁵², such as near-threshold detection. It remains to be seen how our intracerebral data relate to putative markers of consciousness derived from surface EEG²¹.

Our RNN model of the task displayed striking similarities with the human intracerebral data, and allowed us to make causal inferences on the inter-network interactions of the neural clusters we observed. Two distinct components of the attention/consciousness interactions, attentional enhancement and attentional reorienting, clearly emerged in the trained RNN models. The Sustained excitatory units receive the majority of stimuli input and selectively enhance target-related information for conscious report. The Reorienting excitatory units directly receive a smaller branch of visual input. The inhibitory units in the Sustained and Late accumulation RNN clusters receive excitatory input from the Reorienting units. Critically, these results suggest that the right Reorienting neural cluster reorients spatial attention by monitoring the unexpected events in the environment and stopping the ongoing stimulus processing by inhibiting inappropriate activities of other clusters. RNN lesion data further support specific causal contributions of the identified neural clusters and their associated SLF networks in modulating conscious report of near-threshold stimuli. Our model predictions are consistent with neuroimaging evidence showing the involvement of right-hemisphere FP networks in attentional enhancement⁵³ and inhibitory control^{12,54}. Additionally, a previous simulation study of physiological leftward bias (pseudoneglect) found a similar excitatory influence of the right ventral attentional network linked by the SLF III on the dorsal attentional network⁵⁵. Our results extended this prediction to an excitatory-inhibitory neuronal interaction with conscious report, at least for detecting near-threshold stimuli. Strong inter-regional excitation, balanced by local inhibition, can enable reliable sensory signal propagation to the PFC, which in turn can lead to global ignition⁵⁶ and pave the path to conscious visual processing, consistent with the global neuronal workspace hypothesis⁵⁷. More direct causal evidence of the interplay of these FP attentional networks for conscious perception comes from the finding that damage to the right dorsal PFC and decreased microstructural integrity of the SLF III impaired the conscious perception of near-threshold information⁵⁸.

Taken together, the observed interactions between exogenous attention and conscious report support current models of consciousness, which explicitly conceptualize the role of attention in consciousness, such as the gateway hypothesis¹⁶, and the global neuronal workspace hypothesis¹⁷. Both theories postulate that the dorsal FP attentional network gates the way to conscious access, which our findings support and extend also to the ventral attention network. However, our current study was not designed to directly disentangle current theories of consciousness, and other results may not be in total disagreement with the remaining theories (e.g., Integrated information or Recurrent processing). For instance, we observed an early activation of the high-level visual cortex for the consciously perceived targets, a finding potentially in line with the Recurrent processing theory. Our findings specify the temporal dynamics and computational mechanisms underlying attention and consciousness interactions. More generally, our results shed light on the role of dorsolateral, ventrolateral and orbital PFC as well as high-level visual cortex, in human conscious report of near-threshold targets. Previous work on non-human primates showed that reported stimuli were associated with strong sustained PFC activity⁵⁹. However, this late

extensive PFC activity might reflect decision-making instead of conscious experience^{21,22}. Our findings reconcile this debate by demonstrating, on the one hand, the late accumulation activity in right FP areas connected by SLF I–III, which lasted until target report; on the other hand, our results also show the sustained activity for consciously reported target in left PFC and right FP areas connected by SLF II–III, independent of decision time.

The present study has some limitations. First, the use of a subjective conscious report task to probe conscious perception, in which participants had to choose between three alternatives indicating the perceived location of the target (left or right) or its absence. This measure provides information concerning whether participants consciously perceived the target, but it does not provide more subtle information regarding the participants' awareness of their perception, unlike confidence ratings⁶⁰. However, a recent fMRI study using no-report paradigms to dissociate awareness-related neural activation from potential decision-making effects found results consistent with the present ones: activation of FP attention networks was independent of task report and eye movement activity⁶¹. Second, patients were instructed to maintain central fixation, but the clinical setting did not allow us to use eye-tracking recording. Third, our subjects had chronic epilepsy, although contacts with epileptic activity were excluded from analysis. Fourth, cortical coverage was necessarily limited (e.g. in the superior parietal cortex), because it was obviously only determined by clinical needs. The limited and uneven brain coverage across patients also restricted our ability to analyze between-patient variability. However, assessing between-patient variability would not be informative regarding the generalizability of the findings to the neurotypical brain, as the patients serve only as a model for studying neurotypical cognition due to the inevitable lack of a neurotypical control group⁶². Last, we didn't have implanted electrodes in thalamus in our patients, thus we have no empirical data regarding, for example, the potential involvement of recurrent thalamocortical loops, which may well be major contributors to conscious processing^{63–66}.

Despite these considerations, the present evidence establishes the neural dynamics of distinct FP networks and high-level visual areas in the attentional modulation of conscious report of near-threshold stimuli, which is one of the hallmark concepts distinguishing different consciousness theories^{11,14}. Our findings establish specific roles for the right-hemisphere SLF II network in the attentional enhancement of near-threshold targets, for the right-hemisphere SLF III network in perceiving previously unattended targets, and confirm the hypothesized role of left-hemisphere dorsolateral PFC in perceptual decision. This attention/consciousness interaction relies on specific excitatory and inhibitory inter-network interaction mechanisms that causally contribute to conscious perception of near-threshold targets. Thus, distinct, hemisphere-asymmetric fronto-parietal networks support attentional gain and reorienting in shaping human conscious experience.

Methods

Participants and intracerebral recordings. We recruited sixteen patients who underwent presurgical evaluation of pharmaco-resistant focal epilepsy with iEEG implantation, at the Department of Neurosurgery of the Hôpital Pitié-Salpêtrière, Paris, France. All participants had normal or corrected-to-normal vision (age mean \pm SD: 35.0 \pm 8.2; 10 women; 14 right-handed) and provided their written informed consent. The implantation of electrodes and the participation of patients to cognitive tasks received approval from local ethic committee (CPP Paris VI, Pitié-Salpêtrière Hospital, INSERM C11-16 (2012–2020); CPP INSERM C19–55). Patients differed in their prescribed medical treatment, which was reduced or stopped after implantation depending on each patient's medical needs and the delay between the surgery and the experimental recording (range 3–14 days). Three patients were excluded from the data analysis due to poor data quality (two patients had corrupted neural data files and one patient had response times inferior to 150 ms in 32% of trials), leaving a total of thirteen patients in the final sample (age

mean \pm SD: 34.7 ± 8.7 ; 7 women; 11 right-handed). Patients were implanted with 4–13 multilead stereotactic depth electrodes (AdTech®, Wisconsin) endowing 4–12 platinum contacts with a diameter of 1.12 mm and length of 2.41 mm, with nickel-chromium wiring. The distance between the centers of two contiguous contacts was 5 mm. The location of electrode implantation was based exclusively on clinical criteria. In five patients the neural activity was recorded with a 128 channels clinical video-EEG recording system (SD LTM 64 BS, Micromed® S.p.A., Italy), sampling at 1024 Hz with a band-pass filter of 0.15–250 Hz. In the other eight patients, the recording was implemented with a Neuralynx system (ATLAS, Neuralynx®, Inc., Bozeman, MO) which allowed recording up to 160 depth-EEG channels sampled at 4 kHz with 0.1 Hz to 1000 Hz band-pass. The patient-dependent least active contact, preferably in the white matter, was selected as the reference electrode.

Experimental task. The stimuli presentation was controlled by E-Prime 2.0 software (SCR_009567) running on a laptop with a 60 Hz refresh rate. Three black boxes (4.9° long and 3.6° large) were arranged around a central fixation point, persisted for the whole duration of the trial, with 6° horizontally separating the central box center from the peripheral boxes' center. The two peripheral boxes were located in the lower visual field, 4° of visual angle under the central box. Figure 1a illustrates the experimental procedure. Participants were instructed to fixate their gaze at the central fixation cross throughout the test and to respond as fast and accurately as possible. Following the appearance of the fixation and the three placeholder boxes for 1000–1500 ms, a peripheral cue consisting of a black dot (1° diameter), with an RGB value of 128/128/128 corresponding to a 50% simple contrast, was presented for 50 ms at the upper external corner of one of the two peripheral boxes. Three-hundred ms after the visual cue onset, a target stimulus was presented for 16 ms in one of the two peripheral boxes (or not presented in catch trials). The target stimuli were tilted Gabor patches with a spatial frequency of 5 cycles and the diameter of 2.5° visual angle, chosen among 12 equally spaced between 0° and 180°, excluding vertical and horizontal orientations. After a 484 ms delay from the target offset, participants performed a 2-alternative forced choice discrimination, indicating the direction of the tilt among two possibilities presented on the screen and distant by 30° from one another (discrimination task). Then a response screen appeared prompting the participants to report the perceived presence or absence of the Gabors (subjective conscious report task), by selecting one of two opposing arrows (indicating the perceived location of the target), or the word “absent” under the arrows. Trials lasted until participant's response or for a maximum of three seconds. Participants performed eight recording blocks, each consisted of 110 randomized trials including 88 target-present trials and 22 target-absent catch trials. Participants were informed that cues were non-predictive, i.e., in target-present trials cues indicated the target location in 50% of trials (validly cued) and the opposite location on the remaining 50% of the trials (invalidly cued). Before the recording blocks, participants performed a target contrast calibration session in order to estimate the individual perceptual threshold contrast for 50% seen targets. The calibration consisted of two randomly interleaved, one-up one-down staircases, converging toward a detection rate of 50%. The same cueing paradigm was used for the staircase procedure and the same contrast was estimated for valid and invalid conditions in the consideration of limited testing time on patients. Staircase stimuli were the same as the main paradigm across all conditions. These stimuli were created with maximum and minimum Michelson contrast of 0.92 (referred to as 100% contrast used in our manipulations) and 0.02 (1% contrast) respectively. In our experiment, the contrast level of the presented target was individually calibrated for each patient, with a typical contrast range of 10 to 25%. We asked each patient about their subjective perception of the cue; patients explicitly reported that the cue was easily perceived and always visible along the experiment. Additionally, looking at the visual activations for the Cue and for the near-threshold Target, the Cue elicited stronger neural activation than the Target (see Supplementary Fig. 2d), supporting the fact that the Cue was more visible than the Target. Since the Target was adaptively set to be at the threshold of perception, then the Cue should always have been above this threshold.

Behavioral analysis. For each participant, we first excluded trials with RT faster than 150 ms or exceeding three standard deviations. Statistical tests in behavioral analysis were performed using JASP software (version 0.16.0.0, <https://jasp-stats.org/>). We performed a two-way ANOVA with the factors of cue validity and conscious report (in the subjective conscious report task) on the discrimination accuracy. RTs analysis was not reported since participants had to wait for the response screen to give their responses.

Using a nonparametric measure⁶⁷, we conducted SDT analysis⁶⁸ to evaluate the bias produced by the cue validity on participants' perceptual sensitivity a' . We computed the mean percentage of seen targets when the Gabor was presented (Hits) and when the Gabor was absent (false alarms; FA). The criterion C summarizes the distance of the threshold relative to the noise distribution from the threshold of an ideal observer. A smaller value of C represents a more liberal threshold in target detection.

$$a' = 0.5 + (\text{Hits} - \text{FAs}) * (1 + \text{Hits} - \text{FAs}) / [4 * \text{Hits} * (1 - \text{FAs})] \quad (1)$$

$$C = -(Z(\text{Hits}) + Z(\text{FAs})) / 2 \quad (2)$$

We compared detection rate, false alarm rate, sensitivity, and criterion between valid and invalid trials with paired sample t -test.

iEEG preprocessing. Spatial localization of each electrode was recovered using the Epiloc toolbox⁶⁹ developed by the STIM engineering platform in the Paris Brain Institute (<https://icm-institute.org/en/cenir-stim>) with co-registered pre-implantation 1.5 T or 3 T MRI scans and post-implantation CT and MRI scans. After the normalization of MRI-pre, MRI-post and CT-post into the MNI space, contact localization was automatically labeled referring to Desikan-Killiany-Tourville atlas parcellation⁷⁰ in the patient's native space, using Freesurfer image analysis suite (<https://surfer.nmr.mgh.harvard.edu/>) embedded in the Epiloc toolbox, followed by a manual verification and correction, if necessary. Figure 1c and Supplementary Table 1 show the localization of usable contacts referring to Desikan-Killiany-Tourville atlas parcellation: 29 contacts (4%) from occipital, 332 (46%) from temporal, 78 (11%) from parietal, 202 (28%) from frontal, 24 (3%) subcortical and 62 (9%) in white matter. There were 288 contacts in the left hemisphere and 439 contacts in the right hemisphere.

Signal preprocessing was conducted using Matlab (R2018b, The MathWorks, Inc.) and FieldTrip toolbox (fieldtrip-20210529)⁷¹. First, all signals were down sampled to 512 Hz and all contacts were re-referenced to their adjacent neighbor contact on the same electrode, yielding a bipolar montage, in order to ensure that iEEG signals could be considered as originating from a cortical volume centered within the two contacts. Coordinates of bipolar contacts were computed as the mean of the MNI coordinates of two adjacent contacts composing the bipole. An initial visual inspection of continuous signals was performed to remove time segments showing transient epileptic or interictal activity. Contacts with excessive epileptic spikes or near suspected epileptic focus were also rejected. We extracted time courses from −1300 to 1200 ms around target onset for trial epochs. A second artifact inspection was performed on the epoched data, where trials and contacts with excessive maximal signal, z value, variance or kurtosis of the signal distribution were rejected. After signal preprocessing, 727 of the bipolar contacts out of 887 contacts were retained for further analysis.

We then adopted a pseudo-whole-brain analysis approach, by pooling contacts across all thirteen patients on a standardized brain in MNI space. High-frequency broadband (HFBB) power (70–140 Hz), a proxy of spiking activity of the local neuronal ensemble^{29,30}, but also see³¹, was extracted from each bipolar contact by wavelet time frequency transformation using the Morlet wavelets implemented in Fieldtrip (ft_freqanalysis), in fourteen equally spaced center frequency bands. We kept high-frequency band power time courses from −800 to 1000 ms to target onset to discard the 1/ f signal drop off at the edges. Baseline normalization was applied on each trial by means of a z -score relative to the period in the 200 ms prior to cue onset. Finally, HFBB powers were down-sampled to 100 Hz for further analysis.

Temporal embedding visualization with t-SNE. We visualized neural activities and unit activities in a two-component space by a machine learning visualization approach, t -distributed stochastic neighbor embedding (t -SNE). In neural data, we averaged neural activities across contacts by conditions and time points, of which the resulting matrix served as input to compute temporal embedding. t -SNE was computed by an implementation in Scikit learn 1.0.2 in Python 3. We adopted a perplexity of 30 and a learning rate of 100. The embedding was initiated with the PCA option and optimized upon 1000 iterations, by default. The neural data in each condition was projected to a two-dimensional t -SNE embedding. Thus, the ensemble of time points formed a temporal trajectory of neural activities in a reduced manifold. A larger difference between two trajectory components represented a more distinct neural activity pattern between the two conditions. In RNN simulation, we averaged unit activity across units by condition and time point, and kept the above parameters in computing its t -SNE temporal embedding.

Trajectory k-means clustering. We applied a novel clustering approach based on k -means clustering to classify contacts by their temporal profiles³², implemented through Matlab (R2018b, The MathWorks, Inc.). This data-driven approach was able to capture the prototypical patterns of neural dynamics that might be sensitive to cue validity and seen/unseen reports. We conducted clustering on all bipolar contacts. In each contact, we took the trajectories of the mean target-locked activity across an 8-dimensional condition space (target side, cue validity and seen/unseen report). Activity across conditions was z -scored relative to the distribution of the trials' entire duration. Contacts were then iteratively partitioned (10000 iterations) into 2–12 clusters, in which each contact was assigned to the cluster with the nearest centroid trajectory. This was achieved by minimizing the sum of time-point-by-time-point Manhattan distances across conditions, to quantify trajectories similarity while preserving temporal order. Based on the silhouette evaluation (*silhouette* in Matlab), we adopted a ten clusters solution, which reflected the highest average silhouette score (Supplementary Fig. 2a). The partition of the 13 patients' contacts to clusters is shown in Supplementary Fig. 2b. In order to identify the consistency of clusters across different numbers of clusters K , we inspected clusters' trajectory profiles in each number of clusters. We plotted the trajectories of five clusters that showed significant consciousness effects in the $K = 10$ cluster solution (Supplementary Fig. 2d). The minimal variation of the number of contacts in each cluster demonstrated the stability of the contacts in the five selected clusters across k -means solutions (Supplementary Fig. 2c).

Conscious report and interaction-related neural activity. To explore how our experimental manipulation of attention and consciousness influenced the clusters' neural activity, we performed time-resolved three-way ANOVAs with the factors of target side (left/right), cue validity (valid/invalid), and conscious report (seen/unseen). We tested on HFBB power in both cue-target period (from -300 ms to target) and post-target period (from target onset to 500 ms), across contacts on each cluster. For each contact, we averaged HFBB power across trials by conditions. Holm-Bonferroni correction was applied over all the time points for multiple comparisons. For clusters showing significant consciousness effect, post-hoc comparisons were performed on time points where the Cue validity \times Conscious report interaction was significant, with Holm-Bonferroni correction. Further, in order to compare the degree of attentional enhancement across clusters that showed higher neural activity for validly cued seen targets, we performed a linear contrast testing around time points where the clusters showed significant effects.

Response time (RT) modulation of neural activity. To understand the functional roles of neural clusters, we related the neural activity to the response time. In each cluster, we pooled trials from all conditions and contacts. We then sorted the trials and binned them into 20 quantiles according to their response time in the discrimination task. We compared RT-bins neural activity using time-resolved one-way ANOVA in a short time window (target onset to 1000 ms, to avoid the influence by the neural activity of the subsequent trial). To specifically test whether higher sustained neural activity was related to the slower response time, we then compared the neural activity of the ten RT bins with slowest response to the neural activity of the 10 RT bins with fastest response. Holm-Bonferroni correction was applied over all the time points. We also visually compared the RT bins sorted neural activity in a longer time window (target onset to 5000 ms) in order to identify the neural activity patterns associated with visual modulation and task report in each cluster.

White matter tracts dissection. We dissected white matter tracts connecting parietal contacts with frontal contacts. We modeled each intracerebral contact by a 3 mm-sphere. In each cluster, we created two region-of-interests, respectively consisting of frontal contacts and parietal contacts. The parcellation of contacts was referred to Desikan-Killiany-Tourville atlas (see details in iEEG preprocessing and Supplementary Table 1 for contact numbers). We used a dataset that includes 176 preprocessed healthy individuals tractography acquired at 7 tesla by the Human Connectome Project team³⁴. We performed tracts filtering in TrackVis toolbox⁷² to obtain tracts connecting frontal contacts and parietal contacts in frontal association tracts³⁵ (three branches of the superior longitudinal fasciculus; uncinate; long and anterior segments of the arcuate fasciculus; inferior fronto-occipital fasciculus). For each cluster, the tractography maps of the 176 healthy individuals were subsequently binarised and then smoothed with a three-dimensional Gaussian filter (full width at half-maximum was 5 mm, equivalent to a sigma of 2.123). To test the presence of tracts across individuals, we used a threshold-free cluster enhancement-based non-parametric test, with 1000 permutations (*randomize* function in FSL) and a height threshold of 0.95 to control significance level at $p < 0.05$. We computed the volumetric ratio of the labeled tracts in each cluster with those of the standard atlas in BCBtoolkit⁷³ (<http://toolkit.biclab.com/>), where we filtered the atlas probabilistic maps with a threshold of 80% to reduce their overlapping.

Task-optimized recurrent neural network model. Recurrent neural networks (RNNs) are networks in which neurons (units) can send and receive feedback to and from each other. Therefore, the activity of the units is affected not only by the current external stimulus, but also by the current state of the network⁷⁴, which makes RNNs ideally suited for computations that unfold over time such as holding the information of cue position or accumulating target-related evidence for decision making. When the trained RNN accomplishes the behavioral task with a performance comparable to the human ones, the RNN hidden unit activities may provide unique insight about its computations in task representation. Moreover, RNN unit activities might also appropriately predict neural processing^{75,76}.

Our RNN model contained a single layer trained with mini-batch gradient descent learned by backpropagation. Before time discretization, the network activity r follows a continuous dynamical equation:

$$\tau \frac{dx}{dt} = -x + f(W_{rec}r + b_{rec} + W_{in}u + \sqrt{2\tau\sigma_{rec}^2}\xi) \quad (3)$$

$$r = f(x) \quad (4)$$

$$z = W_{out}r + b_{out} \quad (5)$$

where u , x and z denote the input, recurrent state, and output vectors, respectively. W_{in} , W_{rec} , W_{out} are the connection weight matrices of the input layer ($a \times N$ matrix), the recurrent layer ($N \times N$) and the output layer ($N \times 2$). b_{rec} and b_{out} are constant biases into the recurrent and output units. The network is time-discretized with positive activity. dt is the simulation time-step and τ is an intrinsic timescale

of recurrent units which was set to 100 ms. ξ denotes the independent Gaussian white noise processes with zero mean and unit variance, and σ_{rec} is the strength of the noise. f is a nonlinear transfer function, which was set as a rectified linear activation function (ReLU).

Similar to previous studies which trained RNNs to perform cognitive tasks^{77–79}, we abstracted the relevant visual stimuli properties from the patient task (Fig. 1a), rather than feeding the exact same visual inputs to the RNNs. Specifically, visual stimuli from the left and the right fields of view were modeled as two separate noisy inputs (Fig. 4b). The magnitude of the background visual noise along the trial was set as Gaussian noise of the mean of zero and standard deviation of 0.05 . The task began with a fixation period of 200 ms followed by a visual cue randomly presented at either the left or the right side. A target, separated from the cue by a fixed delay period of 300 ms, was then presented on the cued position (validly cued) or on the opposite side (invalidly cued) with equal probability, or absent in 20% of catch trials. After a second fixed delay, the network produced two outputs, each ranging from zero to one, to respond whether there was a target detected. Similar to the human task, RNN outputs were combined to calculate a discrimination and a detection performance. The discrimination accuracy is the ratio of correct response with forced-choice in distinguishing target side when the target were presented. The detection rate equals the ratio of trials in which the network made the correct response about the target presence or absence.

We implemented the model training with PsychRNN⁸⁰, a toolbox backedend by TensorFlow. We adopted the default setting of the package regarding the regularizers (i.e., penalties added to prevent over-fitting to the training data), weight initializer and the loss function (i.e., mean squared error). The noise in each recurrent unit was set to 0.05 . The input, output and recurrent weight was randomly initiated by a glorot gauss distribution from -1 to 1 . The transfer function was rectified linear unit (ReLU). The loss function was defined as the mean squared error. The connections between hidden units were constrained according to Dale's principle: neurotransmitters tend to be either excitatory or inhibitory such that the post-synaptic weights of each recurrent unit are all of the same sign⁷⁸. There were 80% of units fixed to be excitatory and the remaining 20% of units were inhibitory. The strong inhibitory signaling in the recurrent neural network enables stable temporal dynamics⁷⁷. The cue contrast was set as 0.30 SD and we trained RNNs, one at a time, with various target stimulus levels from zero to 0.13 SD, which mimics the near-threshold targets setting in the patient task. The RNNs were trained with 150000 iterations and the model accuracy was tested on 50 batches of 50 sample trials for each target contrast, respectively. Finally, we fitted a psychometric detection curve by logistic function in the subjective conscious report task and in the discrimination task, respectively. To verify the validity of the model, we compared the performance of trained models with an untrained model that was initialized with random Gaussian connectivity weights without feeding stimuli inputs for learning. We also tested RNNs with different hidden units' size (128 , 50 , 32 , and 16) and found out that those RNNs could not achieve human-level performance when the units were less than 16 . To keep sufficient units for further clustering analysis, we adopted the number of hidden units N as 50 to balance the model's complexity and variability.

Trajectory k-means clustering on RNN unit activities. We applied the above-mentioned trajectory clustering method to classify dynamic patterns of the 50 hidden units for intermediate target contrast (0.10 SD). We generated 20 batches of 50 trials (1000 trials in total) and averaged unit activity by condition (all conditions: validly cued seen, invalidly cued seen and no target). Unit trajectories were iteratively partitioned into 2 – 10 clusters across the three-dimensional condition space. The highest averaged silhouette value was obtained while the number of clusters equals five (Supplementary Fig. 4d). We compared seen/unseen trials by time-resolved t -test in the post-target period (target onset to 1000 ms, see Fig. 4d) which could include information after output responses. Holm-Bonferroni correction was applied over all the time points. We also conducted the same k -means clustering analysis on a reduced target contrast (0.03 and 0.06 SD). However, only a late cluster showed a significant consciousness effect. Other clusters may not have reached the significance level because of the low target contrast.

Computing similarity between neural clusters and RNN clusters. In the four neural clusters showing the cue modulation on conscious perception (Visual, Sustained, Late accumulation, and Reorienting), we averaged neural activity in seen and in unseen trials from cue onsets to 500 ms post-targets. We then generated 500 batches of 50 trials with the RNN model simulation for both trained and untrained models. In each batch, we averaged RNN clusters' unit activity in seen and in unseen trials. The similarity was quantified by Pearson correlation coefficient between the RNN clusters' temporal trajectory to the neural cluster ones, with the averaged coefficient of conditions. Therefore, we obtained a distribution of correlation coefficients with 500 samples for the trained and for the untrained models. Finally, we conducted a one-sided permutation test with 1000 permutations to compare the two distributions, in order to identify the RNN clusters being significantly more similar to the neural clusters in the trained model than in the untrained model.

Directed connection weight graph. The iEEG contacts of the neural clusters were pooled from different patients, which limits the possibility to analyze their inter-cluster connections. However, our modeling approach provides the possibility to examine how unit clusters are inter-connected as an integrated model. To this end, we extracted unit input weights, directed unit-to-unit connection weights and output weights of the trained model (Supplementary Fig. 4e). In each cluster, we observed both excitatory (E) and inhibitory (I) type units, of which the number was fully task-optimized without any prior. The Sustained cluster contained 16 E and 4 I units. The Late accumulation cluster had six E and two I units. The Reorienting cluster had eight E and three I units. We grouped units of the same E/I type in each cluster, resulting in six groups in total. We then computed a directed cluster connection graph by averaging unit connection weights from one group (pre-synaptic) to each of the other groups (post-synaptic). For example, to compute the connection weight from the Sustained excitatory group (16 units) to the Reorienting excitatory group (8 units), we averaged a total 128 directed unit-to-unit connection weights. One-sample *t*-test was performed with significance level controlled at $p < 0.05$, Holm-Sidak corrected for multi-comparison among groups of units.

RNN units lesion analysis. In order to ascertain the functional roles of the clusters, we conducted lesion experiments where we individually disabled units within each cluster and observed the resulting decrease in task performance. This was achieved by setting unit's connection weights with inputs, all recurrent units and output to zero. We tested the task performance of the lesioned models with generated 50 batches of 50 trials.

Statistics and reproducibility. We analyzed data from $N = 13$ epileptic patients. The task was implemented using E-Prime 2.0 software (SCR_009567). Intracranial data were processed using Matlab (R2018b, The MathWorks, Inc.) and FieldTrip toolbox (fieldtrip-20210529). Tractography data were processed using TrackVis toolbox (<https://trackvis.org/>) and BCBtoolkit (<http://toolkit.biclab.com/>). The RNN simulation was performed using PsychRNN (<https://github.com/murraylab/PsychRNN>, version PsychRNN-1.0.0).

Reporting summary. Further information on research design is available in the Nature Portfolio Reporting Summary linked to this article.

Data availability

Source data for the plots and graphs in the figures are available as Supplementary Data 1. The intracranial data that support the findings of this study are available from the corresponding author J.L. upon reasonable request.

Code availability

The custom codes for trajectory k-mean clustering analysis and recurrent neural network simulation are available at the Github <https://github.com/jianghao-liu/attention-conscious-report>, with the identifier⁸⁰ <https://doi.org/10.5281/zenodo.8113973> (<https://zenodo.org/badge/latestdoi/658009571>).
