

Comparison of two superconducting phases induced by a magnetic field in UTe_2

W. Knafo ^{1✉}, M. Nardone¹, M. Vališka ^{2,3}, A. Zitouni¹, G. Lapertot ², D. Aoki^{2,4}, G. Knebel ² & D. Braithwaite ²

Superconductivity induced by a magnetic field near metamagnetism is a striking manifestation of magnetically-mediated superconducting pairing. After being observed in itinerant ferromagnets, this phenomenon was recently reported in the orthorhombic paramagnet UTe_2 . Here we explore the phase diagram of UTe_2 under two magnetic-field directions: the hard magnetization axis \mathbf{b} , and a direction titled by $\simeq 25\text{--}30^\circ$ from \mathbf{b} in the (\mathbf{b}, \mathbf{c}) plane. Zero-resistivity measurements confirm that superconductivity is established beyond the metamagnetic field H_m in the tilted-field direction. While superconductivity is locked exactly at fields either smaller (for $\mathbf{H} \parallel \mathbf{b}$), or larger (for \mathbf{H} tilted by $\simeq 27^\circ$ from \mathbf{b} to \mathbf{c}), than H_m , the variations of the Fermi-liquid coefficient in the electrical resistivity and of the residual resistivity are similar for the two field directions. The resemblance of the normal states for the two field directions puts constraints for theoretical models of superconductivity and implies that some subtle ingredients must be in play.

Unconventional superconductivity is observed in an ever-growing number of correlated-electron systems¹, ranging from heavy-fermion^{2,3}, high-temperature cuprate⁴, iron-based pnictide and chalcogenide⁵, to the newly discovered nickelate⁶ and graphene-superlattice⁷ families. New unusual superconducting phases continue to be discovered, such as those reported during the last two decades in the ferromagnets UGe₂, URhGe, and UCoGe^{8–10} with orthorhombic crystal structures. Instead of antiferromagnetic fluctuations, which are suspected to be the glue for superconductivity and to lead to a singlet order parameter in most heavy-fermion superconductors³, ferromagnetic fluctuations were proposed to drive the pairing mechanism of these ferromagnets, where the strong exchange field suggests that a spin-triplet superconducting order parameter with equal-spin pairing may be realized¹¹. Nuclear-magnetic-resonance (NMR) experiments brought microscopic support for such triplet state and they further highlighted the role of magnetic fluctuations^{12,13}. In these three systems, a magnetic field also leads to a re-entrance or reinforcement of superconductivity, and magnetic-field-induced ferromagnetic fluctuations are suspected to directly control the pairing strength, which can be qualitatively understood as the enhancement of a strong-coupling superconducting parameter λ with field¹¹. A S-shape in the temperature dependence of the superconducting critical field H_{c2} was observed in UGe₂ under pressure with a magnetic field along the easy magnetization axis **a**¹⁴. Re-entrance or reinforcement of superconductivity occurs in the isostructural ferromagnets URhGe and UCoGe under a magnetic field applied along their hard-magnetic axis **b**^{15,16}. In URhGe, field-induced superconductivity coincides with a metamagnetic transition at $\mu_0 H_m = 12$ T, where enhanced magnetic fluctuations^{17,18} accompany a sudden rotation of the magnetic moments (from the initial easy direction **c** to the direction **b**)¹⁵. In this system, a Fermi-surface instability is observed at H_m , beyond which a polarized paramagnetic (PPM) regime is established^{19–21}. In UCoGe, the situation is more subtle, since a metamagnetic transition occurs at a field $\mu_0 H_m \approx 50$ T much higher than that of ≈ 15 T at which the reinforcement of superconductivity is observed²².

Recently, superconductivity was found to develop in the paramagnetic heavy-fermion material UTe₂ at temperatures below $T_{sc} = 1.6$ K^{23,24}. This system crystallizes in an orthorhombic crystal structure with space group *I*mmm (#71, D_{2h}^{25}) and is characterized by an anisotropic magnetic susceptibility [see Fig. 1(a)]. No sign of

long-range magnetic order has been found down to the lowest temperatures (25 mK)²⁵. For a magnetic field applied along the easy magnetic axis **a**, a large low-temperature magnetic susceptibility and a scaling plot of magnetization data were interpreted as the indication for a nearby ferromagnetic instability²³. Following the observation of a large anisotropic upper critical field, which exceeds the normal paramagnetic limitation for all field directions^{23,24} and of a tiny change in the NMR Knight shift through T_{sc} ²⁶, a spin-triplet nature of superconductivity has been proposed²³. The possibility of chiral spin-triplet superconductivity was suggested from scanning tunneling microscopy²⁷ and Kerr-effect experiments²⁸. However, while magnetic fluctuations were observed by NMR²⁹ and muon-spin relaxation measurements²⁵, evidence supporting their ferromagnetic nature is still lacking. Furthermore, the presence of antiferromagnetic fluctuations has been reported by inelastic neutron scattering³⁰.

In UTe₂ at temperatures $T < T_{CEP} \approx 7$ K, a magnetic field applied along the hard-magnetic axis **b** induces a first-order metamagnetic transition at $\mu_0 H_m \approx 35$ T, which separates a low-field correlated paramagnetic (CPM) regime from a high-field PPM regime^{31–33}. It is accompanied by sudden jumps $\Delta M \approx 0.3–0.6 \mu_B/U$ in the magnetization^{31,33} and $\Delta \rho \approx 100 \mu\Omega$ cm in the residual resistivity³², and by a large enhancement of the effective mass at H_m ^{31,32,34}. An empirical and almost universal relation $1 T \leftrightarrow 1 K$ between H_m and the temperature $T_{\chi}^{\max} \approx 35$ K at the maximum in the magnetic susceptibility³⁵ is observed, as for a large number of heavy-fermion paramagnets³⁶. It indicates that the CPM regime delimited by H_m and T_{χ}^{\max} is, within a first approximation, controlled by a single energy scale. For **H** || **b**, superconductivity is reinforced above 15 T and it abruptly disappears in the PPM regime above H_m ^{33,37}. Calorimetric studies showed the appearance of a second superconducting phase, labeled by SC2, under pressure in zero magnetic field³⁸. A boundary between SC2 and the ambient-pressure and low-field superconducting phase SC1 was observed from tunnel-diode-oscillator measurements under pressure and magnetic field **H** || **b**³⁹. The extrapolation of this boundary for $p \rightarrow 0$ suggests that the superconducting phase SC2 induced under pressure and the superconducting region induced by a magnetic field **H** || **b** could be the same phase. In the following, we will label SC1 and SC2 the respective low-field and high-field superconducting regions for **H** || **b**. However, to date there is no definitive experimental evidence of a magnetic-field-induced transition between SC1 and

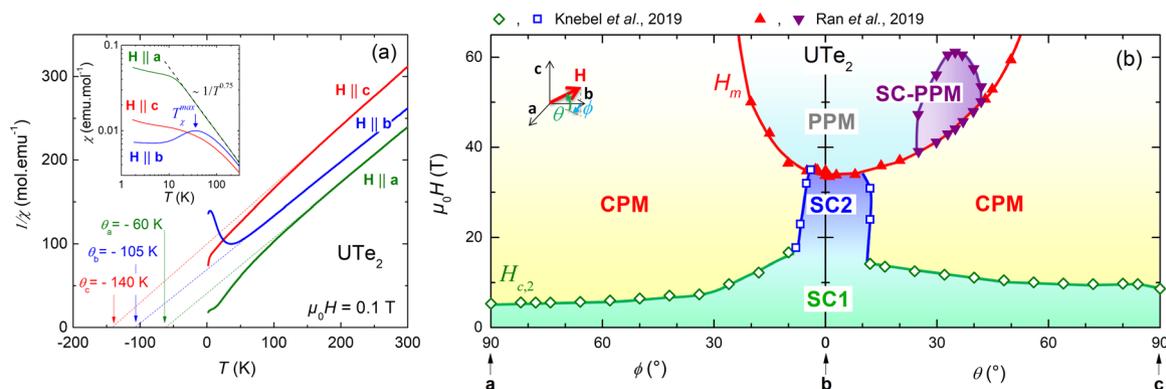

Fig. 1 Magnetic susceptibility and phase diagram of UTe₂. **a** Temperature-dependence of the inversed magnetic susceptibility $1/\chi$ of UTe₂ in magnetic fields **H** applied along the three main crystallographic directions **a**, **b**, and **c**. Inset: Temperature-dependence of the magnetic susceptibility χ for **H** || **a**, **b**, and **c**, in a log-log scale. **b** Low-temperature magnetic-field versus angle phase diagram of UTe₂, in fields applied along variable directions from **b** to **a** (angle ϕ) and from **b** to **c** (angle θ). Two low-temperature paramagnetic regimes and identified: correlated paramagnetism (CPM) and polarized paramagnetism (PPM). SC1 is the low-field superconducting phase, and SC2 and SC-PPM are the superconducting phases induced by magnetic fields **H** || **b** and **H** tilted by $27 \pm 5^\circ$ from **b** in the (**b**, **c**) plane, respectively. H_{c2} is the critical superconducting field and H_m is the metamagnetic field. Data from by Ran et al.³³ and Knebel et al.³⁷ were plotted in this Figure.

SC2 at ambient pressure. An alternative picture without phase transition between SC1 and SC2 cannot be excluded, since the upturn of H_{c2} could result from a tight balance between the orbital limitation and the increase of the coupling λ with field³⁷. We further note that, at ambient pressure and zero magnetic field, a single superconducting transition was identified in^{23,24,40} but two separated superconducting transitions were reported in^{28,41}.

Figure 1(b) presents a combination of low-temperature magnetic-field versus field-angle phase diagrams of UTe_2 obtained by Ran et al.³³ and Knebel et al.³⁷ It summarizes the effect of magnetic fields applied in the (a, b) and (b, c) planes. A key property is that H_m is minimum for $\mathbf{H} \parallel \mathbf{b}$. It strongly increases when the field is tilted from \mathbf{b} towards the easy magnetic axis \mathbf{a} , and exceeds the maximum applied field (60 T) for $\phi = (\mathbf{b}, \mathbf{a}) > 20^\circ$. The increase of H_m is softer when the field is tilted from \mathbf{b} towards \mathbf{c} , where it could be followed up to angles $\theta = (\mathbf{b}, \mathbf{c}) \approx 50^\circ$. At small angles ϕ and θ , the field-reinforcement of superconductivity rapidly disappears. For the three field-directions \mathbf{a} , \mathbf{b} , and \mathbf{c} , the low-temperature critical fields $\mu_0 H_{c2,a} \approx 6$ T, $\mu_0 H_{c2,c} \approx 10$ T, and $\mu_0 H_{c2,b} \approx 15\text{--}20$ T (i.e., the extrapolated value of $\mu_0 H_{c2,b}$ ignoring the field-reinforcement below 300 mK) delimiting the low-field superconducting phase SC1 are inversely-correlated with the low-temperature magnetic susceptibilities $\chi_a > \chi_c > \chi_b$ (see Fig. 1 and refs. 23,31,35). A similar inverse relation between the magnetic anisotropy and the anisotropy of H_{c2} was observed in many other heavy-fermion superconductors, such as URu_2Si_2 ^{42,43}, CeCoIn_5 ^{44,45}, UCoGe and URhGe ^{11,46}. Spectacularly, a second field-induced superconducting phase was reported in UTe_2 for a field tilted from \mathbf{b} towards \mathbf{c} by an angle $20 < \theta < 40^\circ$ ³³. This phase, labeled here as SC-PPM, was observed only in the PPM regime, in fields higher than $\mu_0 H_m \approx 40\text{--}45$ T and up to more than 60 T³³.

In the present work, we focus on a study by electrical resistivity of the superconducting phases SC2 and SC-PPM induced in UTe_2 at ambient pressure, under a magnetic field applied either along \mathbf{b} , or tilted by an angle $\theta \approx 27 \pm 5^\circ$ from \mathbf{b} towards \mathbf{c} . In the initial report of the SC-PPM phase, the electrical resistivity was not exactly zero, likely due to a phase issue in the pulsed-field measurement and to deviations from isothermal measurements resulting from the use of fastly varying pulsed magnetic fields³³. The almost isothermal conditions of our experiments using long-duration (rise = 70 ms, fall = 300 ms) magnetic-field pulses allow studying temperature-dependent effects in a high magnetic field. Our results show zero resistance in the SC-PPM phase, confirming its superconducting nature. We extract the full magnetic-field-temperature phase diagrams of UTe_2 for $\mathbf{H} \parallel \mathbf{b}$ and \mathbf{H} tilted by $\theta \approx 27^\circ$ from \mathbf{b} to \mathbf{c} . From a Fermi-liquid analysis we also determine the field-dependence of the residual resistivity ρ_0 and estimate the variation of the effective mass m^* ⁴⁷. These quantities show striking similarities for the two field-directions in contrast with the very different superconducting phase diagrams. In the discussion, elements resulting from experiments are summarized and confronted to the theoretical challenge to understand the nature of the field-induced superconducting phases in UTe_2 .

Results

Low-temperature and high-magnetic-field electrical resistivity.

The magnetic-field variation of the electrical resistivity ρ of UTe_2 single crystals, measured with a current injected along the \mathbf{a} -direction, is presented in Fig. 2. Data obtained for the two magnetic field directions, $\mathbf{H} \parallel \mathbf{b}$ and \mathbf{H} tilted by $\theta = 27 \pm 5^\circ$ from \mathbf{b} in the (b, c) plane are shown in Fig. 2(a–b) and Fig. 2(c–d), respectively, for a large range of temperatures varying from 200 mK to 80 K. A comparison of field-up-sweep and down-sweep data (see Supplementary Note 1 and Supplementary Figs. 1–6) shows almost no heating of the samples by eddy currents in the

low-temperature data, which were obtained in long-duration pulsed magnetic fields. At temperatures from $T = 2.2$ K to $T_{\text{CEP}} \approx 5\text{--}6$ K, at which a critical end-point is observed in the data, and under magnetic fields $\mathbf{H} \parallel \mathbf{b}$ (Fig. 2(a)) and \mathbf{H} tilted by $\theta = 27 \pm 5^\circ$ (Fig. 2(c)), similar and sharp first-order step-like increases of ρ are observed at $\mu_0 H_m$, which equals 34 and 45 T for the two field directions, respectively. For both directions, when the temperature is increased above T_{CEP} , the sharp anomaly at H_m changes into a broad maximum, at a field also labeled H_m , which vanishes at temperatures higher than 30 K.

Figure 2(b) shows that, for $\mathbf{H} \parallel \mathbf{b}$, field-induced superconductivity develops just below H_m , with an onset at a maximal temperature of 1.2 K and a zero-resistivity reached below the maximal superconducting temperature $T_{\text{SC}} \approx 1$ K. In spite of a non-zero-resistivity due to small out-of-phase contamination of the signal, this new set of data confirms, in magnetic fields extended up to 60 T, the two recent reports of field-reinforcement of superconductivity in UTe_2 for $\mathbf{H} \parallel \mathbf{b}$ ^{33,37}. For \mathbf{H} tilted by $\theta = 27 \pm 5^\circ$ from \mathbf{b} in the (b, c) plane, Fig. 2(d) shows a zero-resistivity regime in fields higher than H_m . These data support the presence of a field-induced superconducting phase SC-PPM above H_m ³³. After an onset at a maximal temperature of 2 K, zero-resistivity is reached below the maximal superconducting temperature $T_{\text{SC}} \approx 1.5$ K, which is higher than the superconducting temperature reported for the field-induced phase for $\mathbf{H} \parallel \mathbf{b}$. The magnetic field at which the zero-resistivity superconducting phase SC-PPM develops is locked to the value $\mu_0 H_m \approx 45$ T observed for $T > T_{\text{SC}}$. Inside the CPM regime, the onset of the phase SC-PPM at ≈ 43 T precedes the zero-resistivity-state reached beyond H_m . We also confirm that the low-field superconducting phase SC1 is well-separated from the field-induced phase SC-PPM. At the lowest temperature, the phase SC1 vanishes at a moderate critical field of ≈ 10 T (see Fig. 1b).

Temperature-magnetic field phase diagrams and quantum critical fluctuations.

Figure 3(a) presents the magnetic-field-temperature phase diagram extracted here for UTe_2 in a field $\mathbf{H} \parallel \mathbf{b}$, in agreement with ref. 37. Although the field-induced transition between SC1 and SC2 was not observed so far at ambient pressure, the phase diagram suggests that two different superconducting regimes exist with a transition or crossover at ≈ 15 T. The transition temperature T_{SC} of SC2 is maximal at a magnetic field just below $\mu_0 H_m = 34$ T. SC2 is presumably driven by the magnetic fluctuations induced on approaching the metamagnetic transition. These fluctuations also control the enhancement of the Sommerfeld coefficient γ in the heat capacity³⁶ and of the coefficient A of the Fermi-liquid T^2 term of the electrical resistivity³². We confirm here that SC2 is strictly bounded by H_m , at which the magnetization was found to suddenly increase and above which a PPM regime is reached^{31,33}.

Figure 3(b) presents the magnetic field - temperature phase diagram extracted here for UTe_2 in a field \mathbf{H} tilted by $\theta = 27 \pm 5^\circ$ from \mathbf{b} in the (b, c) plane. While the low-field superconducting phase SC1 vanishes at a critical field $\mu_0 H_{c2} \approx 10$ T, $\mu_0 H_m$ reaches 45 T at low temperature for this field direction. When the temperature is increased, the behavior is similar to that reported for $\mathbf{H} \parallel \mathbf{b}$: H_m loses its first-order character at the temperature $T_{\text{CEP}} \approx 5\text{--}6$ K. It transforms into a crossover at higher temperatures and finally disappears above 20–30 K. In agreement with the previously-published data³³, the superconducting phase SC-PPM is only observed in fields higher than H_m , and up to a superconducting critical field higher than 60 T at low temperature. A maximal field-induced superconducting temperature $T_{\text{SC}} \approx 1.5$ K appears at a field close to H_m , emphasizing a direct link with the metamagnetic transition.

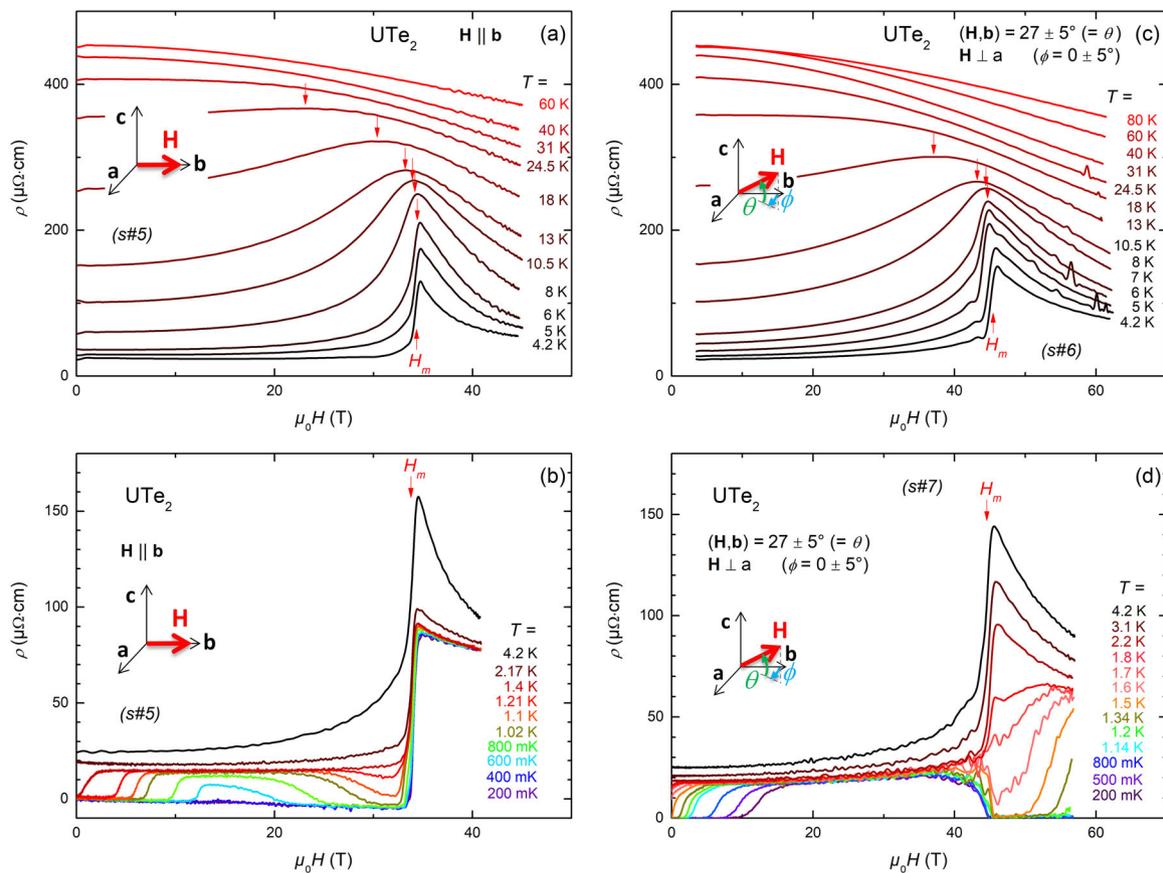

Fig. 2 Electrical resistivity of UTe_2 versus magnetic field. **a** High-temperature and **b** low-temperature resistivity of UTe_2 in a magnetic field $\mathbf{H} \parallel \mathbf{b}$. **c** High-temperature and **d** low-temperature resistivity of UTe_2 in a magnetic field \mathbf{H} tilted by $27 \pm 5^\circ$ from \mathbf{b} in the **(b, c)** plane.

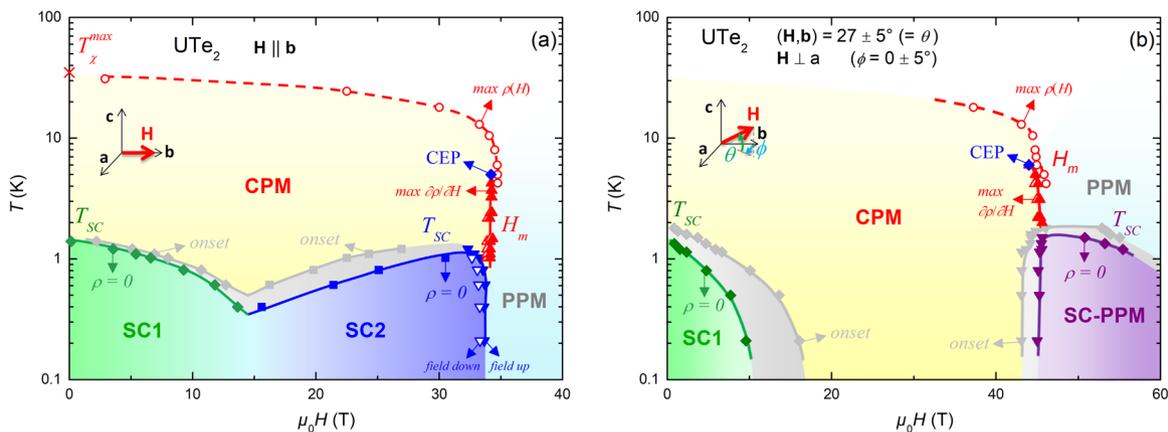

Fig. 3 Magnetic phase diagrams of UTe_2 . **a** Magnetic-field-temperature phase diagram of UTe_2 in a magnetic field $\mathbf{H} \parallel \mathbf{b}$. **b** Magnetic-field-temperature phase diagram of UTe_2 in a magnetic field \mathbf{H} tilted by $27 \pm 5^\circ$ from \mathbf{b} in the **(b, c)** plane. Two low-temperature paramagnetic regimes are identified: correlated paramagnetism (CPM) and polarized paramagnetism (PPM). SC1 is the low-field superconducting phase, and SC2 and SC-PPM are the superconducting phases induced by magnetic fields $\mathbf{H} \parallel \mathbf{b}$ and \mathbf{H} tilted by $27 \pm 5^\circ$ from \mathbf{b} in the **(b, c)** plane, respectively. T_{SC} is the critical superconducting temperature, T_{χ}^{\max} is the temperature at the maximum of the magnetic susceptibility, and H_m is the metamagnetic field. For the superconducting phases, colored points indicate the temperature at which zero-resistivity is reached and gray points indicate the temperature at the onset of the downwards deviation of the resistivity. CEP indicates the critical end-point of the first-order metamagnetic transition.

In many heavy-fermion magnets, a maximum of the effective mass is observed in the vicinity of a magnetic instability. It is commonly understood as resulting from the critical quantum magnetic fluctuations, coupled or not with a Fermi-surface instability⁴⁸. Within a Fermi-liquid description, the electrical resistivity can be fitted by $\rho(T) = \rho_0 + AT^2$, and the A coefficient varies as the square of the effective mass m^* . A Fermi-liquid

picture is generally valid within first approximation, and deviations from the empirical law $A \propto m^{*2}$ can result from additional electronic effects, such as changes in carrier scattering, Fermi-surface and band structure, field-induced cyclotron motion of the carriers, etc. (see for instance this work⁴⁹). In heavy-fermion systems, m^* is mainly controlled by magnetic fluctuations related with the proximity of quantum magnetic instabilities. In several

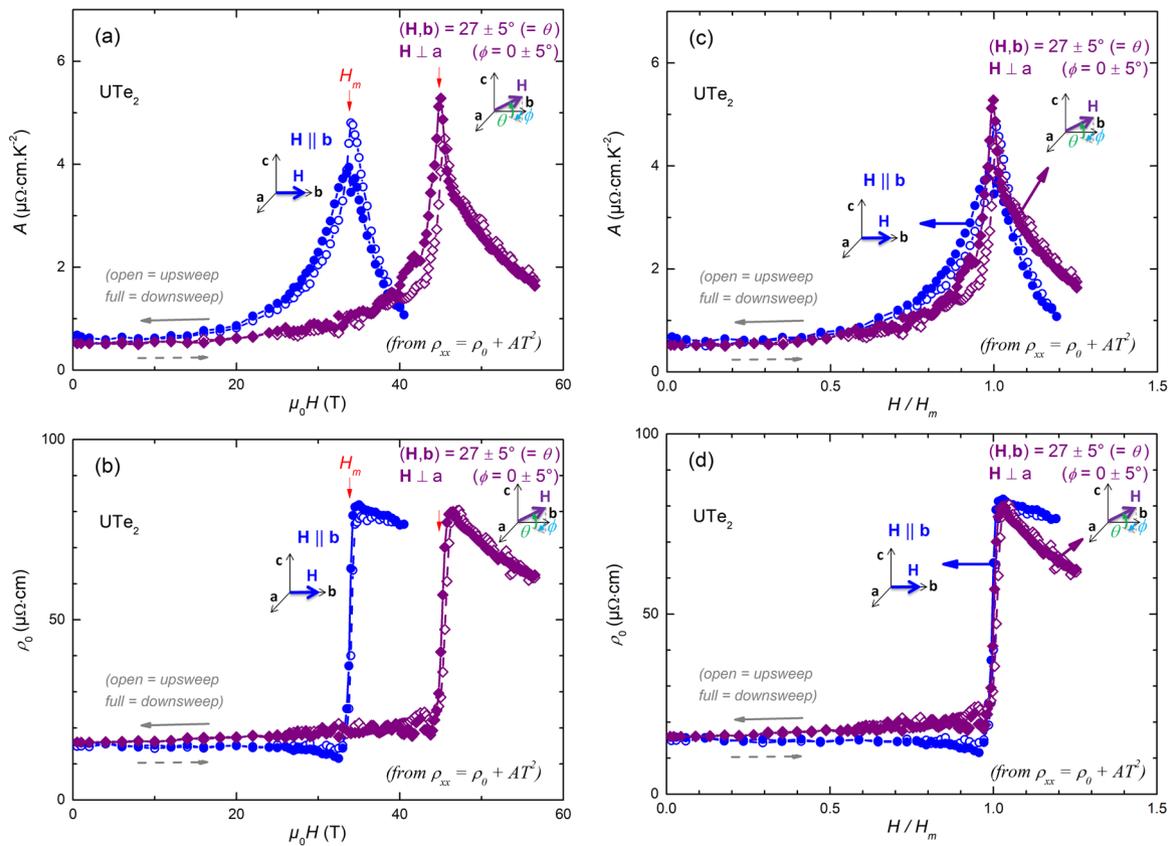

Fig. 4 Quadratic coefficient A and residual resistivity of UTe_2 . **a** Magnetic-field variation of the quadratic coefficient A and **b** residual resistivity ρ_0 extracted from Fermi-liquid fits to the electrical resistivity of UTe_2 in a magnetic field $\mathbf{H} \parallel \mathbf{b}$ and in a magnetic field \mathbf{H} tilted by $27 \pm 5^\circ$ from \mathbf{b} in the (\mathbf{b}, \mathbf{c}) plane. Plots of **c** A and **d** ρ_0 versus H/H_m for the two field-directions. Data are presented for both field-upswEeps and downswEeps. Details about the Fermi-liquid fits are given in Supplementary Note 1 and Supplementary Fig. 7.

compounds, a non-Fermi-liquid deviation from this law is observed near quantum magnetic instabilities⁵⁰. In other compounds, as CeRu_2Si_2 ⁵¹, CeRh_2Si_2 ⁵², and URhGe ²⁰, a T^2 law in $\rho(T)$ was observed down the lowest accessible temperatures at the pressure and/or magnetic-field instabilities. Recently, Fermi-liquid behaviors, including T^2 laws in the electrical resistivity, were reported at the quantum instabilities of UTe_2 under pressure³⁸ and magnetic field $\mathbf{H} \parallel \mathbf{b}$ ^{31,32,34}. In continuity with these studies, fits to the electrical-resistivity data of UTe_2 were done here for all fields investigated in the temperature windows $1.5 \leq T \leq 4.2$ K for $\mathbf{H} \parallel \mathbf{b}$, and $2.2 \leq T \leq 4.2$ K for \mathbf{H} tilted by $\theta = 27 \pm 5^\circ$ from \mathbf{b} to \mathbf{c} (see Supplementary Note 1 and Supplementary Fig. 7). As shown in Fig. 4(a–b), we find almost similar field-variations of A and ρ_0 at H_m for the two field directions: while A increases by a factor ≈ 6 and passes through a maximum, ρ_0 undergoes a sharp step-like enhancement, jumping from 15 to $80 \mu\Omega\cdot\text{cm}$. The field-variation of A reported here for $\mathbf{H} \parallel \mathbf{b}$, in good agreement with a previous report³², indicates a sharp and strong enhancement of the magnetic fluctuations at H_m . For $\mathbf{H} \parallel \mathbf{b}$, a qualitatively similar enhancement of m^* at H_m was found by applying a Maxwell relation to magnetization data³¹ and by direct heat-capacity measurements³⁴.

Small differences between the two field-directions are visible from plots of A and ρ_0 versus H/H_m [Fig. 4(c) and 4(d)]. While the variation of A through H_m is almost symmetric for $\mathbf{H} \parallel \mathbf{b}$, it is slightly asymmetric for \mathbf{H} tilted by $\theta = 27 \pm 5^\circ$ from \mathbf{b} . For the tilted-field direction, $A(H)$ is steeper for $H < H_m$ and more gradual for $H > H_m$. As well, the decrease of ρ_0 beyond H_m is more marked for \mathbf{H} tilted by $\theta = 27 \pm 5^\circ$ from \mathbf{b} . Beyond these small differences, the main result here is the robust finding that the variations of A

and ρ_0 are similar for the two field directions. New high-field experiments on a unique sample, using a rotation probe, are now needed for a complete angular study of the Fermi-liquid behavior.

Discussion

The ultimate goal would be to provide a full microscopic description of the different superconducting phases and their pairing mechanisms in UTe_2 . We are still far from this objective, but the experimental data presented here, in complement to those from ref. 33, offer a broad set of constraints for theories. The role of magnetic fluctuations for superconductivity is indicated by the maximum critical temperature of the reentrant phases observed very near to H_m for both field directions. A striking feature of the phase diagrams presented in Fig. 3(a–b) is that the superconducting phases SC2 for $\mathbf{H} \parallel \mathbf{b}$ and SC-PPM in a field \mathbf{H} tilted by $\theta = 27 \pm 5^\circ$ from \mathbf{b} towards \mathbf{c} are bounded by the metamagnetic field H_m , with a substantial difference that the phase SC2 is pinned inside the CPM regime and it does not survive in the PPM regime while, inversely, the phase SC-PPM is pinned inside the PPM regime and does not develop in the CPM regime. A natural explanation would be that the pairing mechanism changes drastically on crossing the first-order line H_m , at which one would expect a difference in the nature of the critical magnetic fluctuations in the CPM and PPM regimes. This difference would change substantially for the two field-directions $\mathbf{H} \parallel \mathbf{b}$ and \mathbf{H} tilted by 27° from \mathbf{b} .

A rough estimation of the field-dependence of the pairing strength can be obtained from the Fermi-liquid analysis done above. A maximum of the quadratic coefficient A at H_m indicates an increase of the effective mass m^* , presumably controlled by

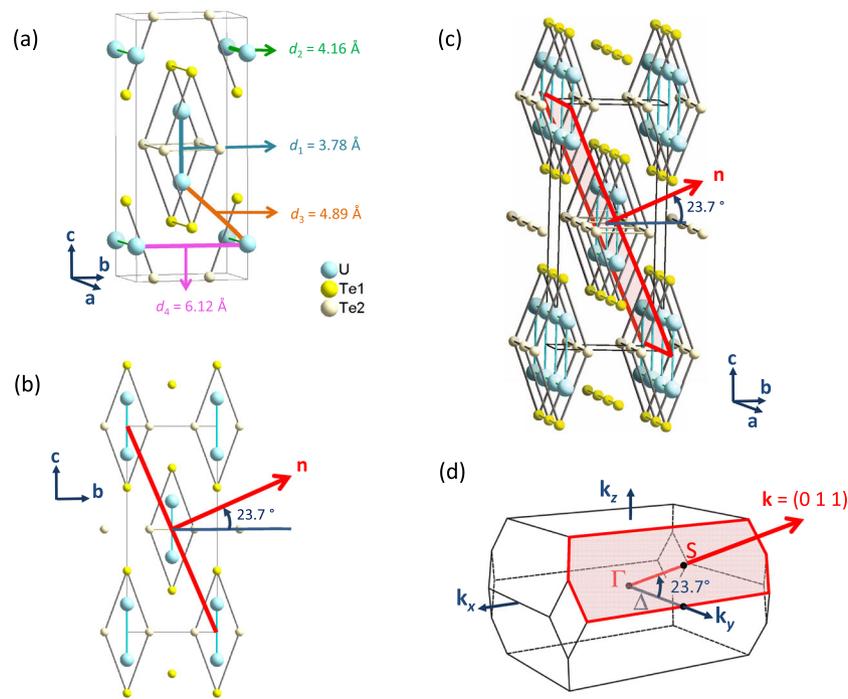

Fig. 5 Crystal structure and Brillouin zone of UTe_2 . **a** Elementary unit cell and identification of the four smallest U-U distances, **b** projection of the lattice structure in the **(b, c)** plane, **c** crystal structure extended to several unit cells emphasizing the network of two-leg ladders, and **d** Brillouin zone of UTe_2 . The vector \mathbf{n} normal to a family of reticular (and cleaving) planes of Miller indices (0 1 1), with an angle $\theta = (\mathbf{b}, \mathbf{n}) = 23.7^\circ$, is indicated. These reticular planes are characteristic of the ladder structure. In reciprocal space, the corresponding wavevector $\mathbf{k} = (0\ 1\ 1)$, expressed in relative lattice units, is perpendicular to two planes of the Brillouin zone boundary.

critical magnetic fluctuations. In the case of URhGe, A is maximum at H_m ¹⁷, where critical magnetic fluctuations were evidenced by NMR¹⁸. A similar symmetrical enhancement of A is observed in many heavy-fermion systems at H_m , where drastic changes of magnetic fluctuations and Fermi surfaces were found^{53,54}. In URhGe under pressure⁵⁵, or in a magnetic field tilted away from \mathbf{b} ¹⁸, H_m increases and the maxima of T_{sc} and of the magnetic fluctuations remain glued to H_m . This suggests that field-reentrant superconductivity is induced by enhanced critical magnetic fluctuations at H_m . In a simple picture, the superconducting pairing strength λ increases as the effective mass m^* in the proximity of H_m ^{56,57}. In UTe_2 , the fact that the enhancement of A is almost symmetric around H_m is puzzling with respect to the abrupt suppression of superconductivity for $\mathbf{H} \parallel \mathbf{b}$, and its abrupt appearance for \mathbf{H} tilted by $\theta = 27 \pm 5^\circ$ from \mathbf{b} towards \mathbf{c} . The abrupt disappearance/appearance of superconductivity at H_m could also result from a sudden change of the Fermi-surface. A Fermi-surface reconstruction is compatible with the large and sudden variation of the residual resistivity ρ_0 at H_m for the two field directions, but also with the sign changes in the thermo-electric power and Hall coefficient at H_m for $\mathbf{H} \parallel \mathbf{b}$ ⁵⁸. However, our results raise a serious hurdle to both these pictures since the field-driven enhancement of A is very similar for $\mathbf{H} \parallel \mathbf{b}$ and \mathbf{H} tilted by $\theta = 27 \pm 5^\circ$ from \mathbf{b} to \mathbf{c} . If it is an intrinsic property, the asymmetry in the field-variation of A for \mathbf{H} tilted by 27° could suggest that the magnetic fluctuations are slightly more intense above H_m for this field direction. However, this effect would be too small to explain the differences between the phases SC2 and SC-PPM. The magnetization jumps at H_m are also very similar for $\mathbf{H} \parallel \mathbf{b}$ and \mathbf{H} tilted by 27° ³³. Extra ingredients are, thus, needed to describe the field and angle domains of stability of these two field-induced superconducting phases.

Figure 5(a–c) presents views of the crystal structure of UTe_2 where the magnetic uranium ions can be seen to form a ladder

structure⁵⁹. We highlight the family of reticular (and cleaving) planes of Miller indices (0 1 1), which contain sets of ladders having the smallest inter-ladder U–U distance ($d_3 = 4.89 \text{ \AA}$). Interestingly, the direction \mathbf{n} normal to these planes coincides, within the experimental uncertainty, with the field-direction along which the phase SC-PPM develops³³. It lies in the **(b, c)** plane and has an angle $\theta = 23.7^\circ$ with \mathbf{b} . Figure 5(d) presents a view of the Brillouin zone. It emphasizes that the direction \mathbf{n} in real space is equivalent to the direction $\mathbf{k} = (0\ 1\ 1)$ in reciprocal space. Although the connection with the pairing mechanism remains unclear, this coincidence may not be accidental and may constitute a possible line of approach for future theories. Indeed, the field-induced superconducting phases SC2 and SC-PPM may be sensitive to fine details of the Fermi-surface topology, in relation with high-symmetry directions. Further experimental studies, with a more accurate positioning of the samples (within misorientations $\Delta\theta, \Delta\phi < 1^\circ$), are now needed to test the robustness of the coincidence observed here.

In relation with the ladder structure, magnetic frustration has been invoked as a possible origin of the paramagnetic ground state in UTe_2 at zero-field and ambient pressure, and a competition between ferromagnetic and antiferromagnetic configurations has been discussed^{59,60}. Electronic-structure calculations pointed out that the ground state is sensitive to the Coulomb repulsion, and that the ferromagnetic and antiferromagnetic configurations are energetically-close⁵⁹. The respective roles of ferromagnetic and antiferromagnetic fluctuations in UTe_2 may, thus, be important for the superconducting phases. While UTe_2 was first proposed to be nearly ferromagnetic²³, the nature of the pressure-induced magnetic phase, initially reported in³⁸, was not determined so far. Several studies suggested that UTe_2 is not a simple nearly-ferromagnet and may be close to an antiferromagnetic instability^{41,61}, which is supported by the observation of antiferromagnetic fluctuations³⁰. At ambient pressure,

the absence of metamagnetism in a magnetic field up to 55 T applied along the easy magnetic axis \mathbf{a} ^{31,32} indicates that UTe_2 is at least not a conventional Ising paramagnet close to a ferromagnetic instability, unlike UGe_2 under pressure⁶² and UCoAl at ambient pressure⁶³. The negative Curie-Weiss temperatures extracted from the high-temperature magnetic susceptibility, for the three directions $\mathbf{H} \parallel \mathbf{a}$, \mathbf{b} , and \mathbf{c} [see Fig. 1(a)], indicate antiferromagnetic exchange interactions (see also ref. 35). A broad maximum at the temperature $T_\chi^{\text{max}} = 35$ K in the magnetic susceptibility for $\mathbf{H} \parallel \mathbf{b}$ is also compatible with the onset of antiferromagnetic fluctuations, as observed in several heavy-fermion paramagnets³⁶. Low-temperature downward deviations of the magnetic susceptibility for $\mathbf{H} \parallel \mathbf{a}, \mathbf{c}$ (in comparison with its high-temperature behavior) are observed in the log-log plot shown in Inset of Fig. 1(a). These deviations confirm the formation of a heavy-fermion state below 50 K, which may coincide with the onset of antiferromagnetic fluctuations, possibly those observed by inelastic neutron scattering³⁰. Interestingly, the high-temperature magnetic susceptibility for $\mathbf{H} \parallel \mathbf{a}$ varies as $1/T^{0.75}$ over more than one decade, from 20 to 300 K. However, further investigations are needed to understand this power-law behavior. Magnetic anisotropy, which drives the preferential direction of the magnetic fluctuations, is also suspected to play a significant role for superconductivity. The inverse relationship between the low-field magnetic anisotropy and the critical fields of the phase SC1 was emphasized in the introduction. The evolution of the magnetic anisotropy in a high magnetic field may also play a role for the stabilization of the field-induced superconducting phases.

The different superconducting regimes may correspond to different order parameters, with different sensitivities to a magnetic field. It has been generally assumed that all the superconducting phases in UTe_2 have a triplet order parameter, mainly because of high values of the superconducting upper critical field, a small decrease of the NMR Knight shift below T_{sc} ²⁶ and a supposed proximity to ferromagnetism^{23,24,59,64}. However, this still needs confirmation especially if, as pointed out above, antiferromagnetic fluctuations may play a much larger role than initially thought. The disappearance of superconducting phase SC2 as the PPM regime is entered for $\mathbf{H} \parallel \mathbf{b}$ could be related to the loss of magnetic fluctuations characteristic of the CPM regime. Thereafter, for \mathbf{H} tilted by $\theta = 27 \pm 5^\circ$ from \mathbf{b} to \mathbf{c} , the phase SC-PPM could be a natural candidate for triplet superconductivity with no paramagnetic limitation. However, two questions remain: why this phase appears only for such a specific angular range, possibly in relation with the previous symmetry considerations, and especially why this phase does not develop in fields smaller than H_m ? Interestingly, other superconducting phases develop in UTe_2 under pressure combined with a magnetic field applied along the easy axis \mathbf{a} ⁶¹, and the resulting isobar magnetic-field-temperature phase diagrams have similar features than that reported for another compound with multiple superconducting phases, UPt_3 at ambient pressure⁶⁵.

A full understanding of the magnetic fluctuations and their feedback on the superconducting pairing undoubtedly requires the knowledge of the Fermi-surface and electronic structure of UTe_2 . As mentioned above, calculated Fermi surfaces strongly depend on the Coulomb repulsion U : for large values of U , two-dimensional Fermi surfaces along \mathbf{c} similar to that of ThTe_2 and corresponding to a localized f -electrons limit have been expected^{59,60,66}. For quasi one-dimensional⁶⁷ or quasi two-dimensional^{68,69} Fermi surfaces, Ginzburg-Landau theories, which neglect the role of magnetic fluctuations, also predict that the orbital limit could be suppressed for particular field directions. However, while angle-resolved-photo-emission-spectroscopy revealed a light low-dimensional band, they also showed the presence of a heavy three-dimensional band centered around

the point Z of reciprocal space⁷⁰. The observation of low-dimensional features in the bulk properties (for instance strongly-anisotropic electrical resistivity) are now needed to support a low-dimensional Fermi-surface model of superconductivity for UTe_2 .

Rich-phase diagrams were obtained for UTe_2 under different field directions and pressures. Although the measurements presented here and in other works^{33,37–39,41,61,71} start to bring a clear picture of the complex phase diagram of UTe_2 , which includes multiple superconducting and magnetic phases, we are still far from a deep understanding of its electronic properties. A target is now to perform microscopic studies to identify the nature of the magnetic fluctuations and their change through H_m . In relation with these magnetic fluctuations, a challenge will be to identify the nearby long-range-ordered magnetic phases. The objective to characterize the Fermi-surface in the different phases is also emphasized. Beyond the need for solid experimental findings, theoretical developments are needed to describe the superconducting pairing mechanism(s) and order parameter(s). This is a stiff challenge, but the rare flurry of stunning phenomena observed in UTe_2 fully justifies such forthcoming efforts.

Methods

Samples. Single crystals of UTe_2 were prepared by the chemical vapor transport method with iodine as transport agent. Their structure and orientation was checked by single-crystal X-ray diffraction. A sharp bulk transition at $T_{\text{sc}} = 1.6$ K was indicated from specific heat measurements, while zero-resistivity at temperatures below T_{sc} was confirmed by zero-field AC resistivity measurements. Samples #5, #6, and #7, whose electrical-resistivity data are presented here, have similar residual-resistivity ratios $\rho(300 \text{ K})/\rho(2 \text{ K}) \approx 25$ to those of samples #1, #2, and #3 studied previously^{32,37}, indicating similar sample qualities.

Pulsed-field experiments. Electrical-resistivity measurements were performed at the Laboratoire National des Champs Magnétiques Intenses (LNCMI) in Toulouse under long-duration pulsed magnetic fields, either up to 68 T (30 ms raise and 100 ms fall) and combined with an ^4He cryostat offering temperatures down to 1.4 K, or up to 58 T (55 ms rise and 300 ms fall) and combined by a home-developed dilution fridge made of a non-metallic mixing chamber offering temperatures down to 100 mK. A standard four-probe method with currents $\mathbf{I} \parallel \mathbf{a}$, at a frequency of 20–70 kHz, and a digital lock-in detection were used. Resistivity data were normalized so that the maximal value, at a temperature of ≈ 65 K and at zero-field, reaches $450 \mu\Omega\text{cm}$ (a different normalization lead to a maximum of $650 \mu\Omega\text{cm}$ in a previous work³²). Normalization was made following absolute resistivity measurements on samples whose geometrical shape was known. The measurements in different field directions were done on different samples, and we cannot exclude that the small differences, as those seen in the variations of A and ρ_0 extracted from a T^2 law, have an extrinsic origin (they could result from a limit of reproducibility in our measurements). Concerning the tilted-field direction, the choice for an angle $\theta \approx 27^\circ$ was made following the initial study made by Ran et al.³³, where electrical-resistivity measurements indicated that the phase SC-PPM is centered at a tilt angle $\theta \approx 23.7^\circ$, while tunnel-diode-oscillator measurements showed that it is centered around $\theta \approx 33^\circ$.
