Direct measurements reveal instabilities and turbulence within large amplitude internal solitary waves beneath the ocean

Ming-Huei Chang¹✉, Yu-Hsin Cheng¹, Yiing Jang Yang¹, Sen Jan¹, Steven R. Ramp², D. Benjamin Reeder³, Wan-Ting Hsieh¹, Dong S. Ko⁴, Kristen A. Davis⁵, Huan-Jie Shao⁶ & Ruo-Shan Tseng⁶

Internal solitary waves are ubiquitous in coastal regions and marginal seas of the world's oceans. As the waves shoal shoreward, they lose the energy obtained from ocean tides through globally significant turbulent mixing and dissipation and consequently pump nutrient-rich water to nourish coastal ecosystem. Here we present fine-scale, direct measurements of shoaling internal solitary waves in the South China Sea, which allow for an examination of the physical processes triggering the intensive turbulent mixing in their interior. These are convective breaking in the wave core and the collapse of Kelvin-Helmholtz billows in the wave rear and lower periphery of the core, often occurring simultaneously. The former takes place when the particle velocity exceeds the wave's propagating velocity. The latter is caused by the instability induced by the strong velocity shear overcoming the stratification. The instabilities generate turbulence levels four orders of magnitude larger than that in the open ocean.

Internal solitary waves (ISWs) are ubiquitous in coastal regions and marginal seas of the world's oceans¹. They are mostly evolved from the nonlinear steepening of internal tides generated when tidal currents flow over abrupt topography, e.g., shelf breaks or submarine ridges. After generation, ISWs are able to persist for a few days traveling hundreds of kilometers until they shoal into shallow water. During the shoaling stage, ISWs can fission into multiple waves, reverse their polarity, and break^{2–6}, all of which induce strong and rapid turbulent dissipation and mixing. It is recognized the turbulence driven by internal tides results in mixed water masses, which subsequently flow into the vast ocean interior⁷ and dissipate a significant amount of energy in the world's oceans⁸. Since ISWs play a role in mediating tidal energy into smaller-scale turbulence, a better understanding of the physics of energy dissipation and mixing throughout ISW evolving from generation to shoaling may contribute to better parameterization of mixing and understanding of the energy

budget in global ocean models and climate models. In ocean environment, energetic currents and turbulence associated with ISWs can re-suspend sediments^{9–13}, alter acoustic transmission^{14–16}, damage offshore engineering structures¹⁷, and influence the ecosystems in the nearshore^{18–20}.

The most vigorous internal solitary waves in the world's oceans have been observed in the South China Sea (SCS)^{4,21–23}, where their horizontal and vertical velocities are larger than 2 and 0.5 m s^{−1}, respectively, and their amplitude can reach 100–200 m^{24–27}. Internal tides generated over the ridges in Luzon Strait are the source of ISWs in the SCS^{27–29} (Fig. 1a). As the internal tides propagate westward across the SCS deep basin, they evolve into more bore-like structures^{30,31} via nonlinear steepening, and are further amplified by the shoaling continental slope. These processes create strong packets of ISWs above the Dongsha plateau (the area between 200 m and 500 m isobaths in Fig. 1a). Strong turbulent dissipation has been observed to be $\sim O(10^{-6}–10^{-4})$ W kg^{−1} when

Fig. 1 Background and overview of observations. **a** Bathymetry and surface signatures of ISW, pointed out by the red arrows, from Moderate Resolution Imaging Spectroradiometer (MODIS) image snapshot at 02:55 A.M. 18 April, 2003, **b** MODIS image snapshot at 02:45 A.M. 18 May, 2019 inside the red dashed box in **a**, **c** cross-section of bathymetry along the yellow line in **b**, and **d** time series of vertical velocity averaged from 150 to 250 m (black curve) at A1, maximum particle velocity within the ISW (red dots) at A1, and propagation speeds of ISWs (blue dots). The horizontal blue, red and green lines in **c** are the ship tracks for the first, second and third shipboard surveys, respectively. The positions of thermistor chain (T1) and ADCP mooring (A1) were 252 m apart, as denoted by the red and black dots, respectively, in **b** and by the red and dashed black vertical lines, respectively, in **c**. The 15 ISW packets observed during May 15–23, 2019 are numbered and labeled in **d**. “RW” and “DW” in **b** denote the reflected waves and diffracted waves, respectively. The gray shade area in **d** represents the 95% confidence interval.

the ISWs shoal^{25,32}, motivating a search for the mechanism by which the energetic ISWs transfer their energy to turbulence. In the present context, ISWs dissipate their energy through turbulence as a result of wave instabilities as the ISWs shoal. Shoaling of an ISW over a steep slope larger than 0.03^{33} (bottom slope angle 1.7°) generally leads to intense wave break (overturning), deformation processes, fission and production of multiple elevation waves (transformation) that propagate up the slope^{4,5,34}, while the instabilities are unclear or absent due to the rapid and intense wave evolution. When an ISW shoals over a relatively gentle slope (bottom slope angle $<1.7^\circ$), it is found the instabilities occur in the waves' interior or in the bottom boundary layer^{11,35,36}. The former includes shear instabilities driven by enhanced vertical shear of horizontal currents^{3,37–42} and convective instabilities in the wave core occurring when the particle velocity exceeds the wave velocity^{6,33,43–47}. A detailed review can be found in ref. ⁴⁸. However, clear signatures of shear and convective instabilities within the ISWs have rarely been observed in the ocean due to their intermittence and rapid evolution.

Nevertheless, field observations using a combination of echo sounding and conductivity–temperature–depth (CTD) profiling on the Oregon Shelf³⁷ and on the Dongsha Plateau in the SCS³ revealed trains of ISWs with clear manifestation of shear instabilities that were the primary source of turbulence. Subsequently, a series of numerical experiments^{40–42,45} and laboratory experiments^{38,39,49} was conducted based on the observations of ref. ³⁷ and ref. ³ to address the generation mechanism and criteria of occurrence for these instability waves. References ⁶ and ⁴⁷ presented observations of a shoaling ISW of depression in the SCS as it underwent the formation of a recirculating trapped core as a result of convective breaking.

Those previous observations were mostly recognized by echo sounder images and hydrographic data with limited resolution and subsequently supplemented by laboratory experiments and numerical simulations. Here, we present observational evidence of Kelvin–Helmholtz (KH) instability and convective overturn and their resultant turbulence within the ISWs using multiple platform measurements (see “Methods”) including a fast-sampling moored thermistor chain (T1) with a vertical resolution of 4–5 m spanning 26–270 m depth, moored acoustic Doppler current profiler (ADCP) (A1), shipboard echo sounder, and shipboard turbulence profiler collected off just east of the Dongsha Atoll in the SCS (Fig. 1b, c). The sampling intervals for the thermistors and ADCP were 10 s and 6 s, respectively, capable of capturing the instabilities within the ISW. A series of 15 ISW packets was measured. All of the leading waves in these packets had maximum particle velocity larger than propagation speed, indicative of convective breaking and the formation of trapped cores. Both the convective overturning and Kelvin–Helmholtz billows were observed and their resultant turbulent mixing was quantified. The observations are used to compare with the previous observations, to examine the results of previous laboratory experiments and numerical simulations, and to assess the competition between shear and stratification, which govern the formation of instabilities and turbulent mixing.

Results

Observed wave properties. In spite of the commonly observed diffracted and reflected waves (Fig. 1b), the present study focuses on the incoming ISWs east of the Dongsha Atoll, where they shoal onto the shallow water near the atoll (Fig. 1b, c). The cross-section of bathymetry along $20^\circ42'N$ east of the atoll (yellow line in Fig. 1b) presents a shallowing continental slope from $117^\circ30'E$ (870 m) to $116^\circ57'E$ (100 m) (Fig. 1c), with a mean slope of 0.013 (bottom slope angle 0.74°). The bottom slope around our

mooring site at 300 m is 0.025 (bottom slope angle 1.43°). As previously mentioned, the slope angle ($<1.7^\circ$) may favor the occurrences of the instabilities in the waves' interior and/or in the bottom boundary layer (BBL). Unfortunately, these observations of temperature and velocity commenced above the BBL were not observed, and consequently were not discussed further. The leading wave of a wave packet, typically the largest and having a vertical velocity of $0.3\text{--}0.5\text{ m s}^{-1}$, was an indicator of the ISW packets in the 9-day moored observations (black curve in Fig. 1d). ISW packets arrived at our moorings primarily at a semidiurnal period, i.e., twice per day. In total, 15 ISW packets, numbered from 1 to 15 in Fig. 1d, were measured by the thermistor chain and ADCP. Propagation speeds (C) of those measured ISWs ranged from 1.0 to 1.5 m s^{-1} (blue dots), and had a mean value of 1.3 m s^{-1} (see “Methods” for the estimate of C). The maximum value of C was 2.1 m s^{-1} during the passage of ISW #10. Maximum particle velocity within the ISW ($U_{\max}$) is shown as the red dots in Fig. 1d. It is found all of the observed ISWs reached the limit of convective breaking⁶, $U_{\max} > C$. The average $U_{\max}$ was 1.7 m s^{-1} , 30% larger than mean propagating speed.

Time-depth contours of the 15 observed leading ISWs are illustrated in Fig. 2 and Supplementary Fig. S1. As a whole, the $18^\circ C$ isotherm (magenta curve) is consistent with a typical mode-1 depression waveform and it effectively divides the ISW into a calm region below it and a very dynamical region above it where the isotherms undulate. The maximum vertical displacement $\eta_{\max}$ estimated from the depression of the $18^\circ C$ isotherm ranged from 76 m (ISW #2) to 125 m (ISW #11) with a mean value of 103 m (black curve in Supplementary Fig. S2a). The horizontal wavelength measured at half of the wave amplitude, i.e., the half-amplitude full width $\lambda_{1/2}$, ranged from 0.53 km (ISW #1) to 1.16 km (ISW #10) with a mean value of 0.79 km (blue curve in Supplementary Fig. S2a). Except for ISW #1, the observed ISWs have an asymmetric waveform characterized by a gently sloping front edge and steepening at the trailing edge. This is because the wave trough slows down with respect to the upper layer currents as the waves shoal^{34,42}. It is a subtle effect in these plots indicating that the waves are just starting to feel the bottom at the 300 m isobath.

KH instabilities and breaking of the waveform. All of the ISWs measured by the thermistor chain revealed different degrees of breaking and undulation along the depressed waveform (Fig. 2 and Supplementary Fig. S1). The breaking pattern of ISWs can be seen mostly at the trailing edge and immediately above the isotherms where the stratification is strong, forming the breaking tail of the ISWs (for example, ISWs #4, #7, #8 and #11 in Figs. 2 and 3). A detailed example of breaking can be found in ISW #4 (Fig. 2a). A train of roll-up thermal patterns on the wave trough with a vertical scale of ~ 15 m is visible. Clearly, the roll-up thermal patterns are KH billows^{50–53}. Following this train, a breaking of waveform encompassing a chaotic thermal patch and numerous overturns occurs in the wave's trailing edge. Note the collapse is not constrained to the leading wave but can extend downstream and affect the following waves. A similar breaking structure can be seen in ISWs #7, #8, and #11 (Fig. 2). However, the features of KH billows near their wave trough are less organized than those observed in ISW #4, presumably because the billows were in an early stage of development or/and their resulting billow size was smaller than our measuring resolution. Comparing our observations with previous observations³⁷ and numerical simulations⁴², the waveform breaking in the trailing edge could be related to the growth and ultimate collapse of the KH billows, mostly in the wave rear. As the propagating speed of the billows is less than the ISW's propagating speed, the age of the billows in a train increases toward the trailing edge of the waves.

Fig. 2 Observed ISW thermal structures and instabilities. Isothermal contour plots of **a** ISW #4, **b** ISW #7, **c** ISW #8, and **d** ISW #11 measured by mooring T1. The black contour line interval in **a–d** is 0.5 °C. The cyan contour lines in **b** range from 26.7 °C to 27.3 °C with an interval of 0.1 °C. The magenta contour line is the 18 °C isotherm. The red dots in **a** are the locations of the temperature sensors. The time axis is relative to the arrival time of the ISWs (see “Methods” for details). The undulation of the upper boundary of the contoured region is because the thermistor chain was bent over by the wave-induced current drag.

The other 11 ISWs shown in Supplementary Fig. S1 depict less apparent breaking in the trailing edge. ISW #6 shows a sequence of KH billows-like structure with a vertical scale of ~10 m in the trough. The largest KH billows appear in ISW #14. A train of four KH billows occupies the ISWs from ahead of the wave trough to the wave trough.

On the whole, the above features are in qualitative agreement with previous field observations based on the echo sounder images (Fig. 5 in ref. ³⁷, Fig. 9 in ref. ³), laboratory experiments (Fig. 10 in ref. ⁴⁹, Fig. 4 in ref. ³⁸, Fig. 3 in ref. ³⁹), and numerical simulations (Fig. 4 in ref. ⁴⁰, Fig. 7 in ref. ⁴¹, Fig. 13 in ref. ⁴², Fig. 13 in ref. ⁴⁵). Having also direct observations of density and velocity at high resolution allows further quantification of the wave breaking process.

The occurrence of the KH instability depends on the competition between shear characterized by S^2 (Methods) and stratification characterized by N^2 (Methods), which tend to destabilize and stabilize the fluid layer, respectively, forming the critical Richardson number $Ri = N^2/S^2$. The canonical criterion for the instability of a parallel stratified shear flow is^{54,55} $Ri < 0.25$, which is not a sufficient condition for instability within the ISW. Instead, laboratory experiments and numerical simulations^{39–42,49} have suggested the conditions under which the shear instabilities within the ISW occur (curved stratified shear flow) include (1) $Ri < 0.1$ and (2) $L_x/\lambda_{\eta/2} > 0.86$, where L_x is the length scale of the unstable region in which $Ri < 0.25$ and $\lambda_{\eta/2}$ is the half-amplitude full width (half width) of ISW. The conditions (1) and (2) allow the instabilities to have sufficient time to grow and eventually form KH billows. For ISWs #4, #7, #8, and #11 (Fig. 3), the shear squared S^2 is found to be mostly stronger along the lower

periphery of the wave core and occasionally extended to the wave core. The stronger stratification characterized by N^2 is located predominantly below the periphery of the wave core. As a result, the region satisfying $Ri < 0.25$ (yellow contour line) are predominantly along the lower periphery of the wave core and slightly above the layer of strong stratification (second row in Fig. 3). The similar distribution of Ri in the waves can be found in the other ISW events (Supplementary Fig. S3). Only ISWs #1, #2, and #5 have the minimum Ri value larger than 0.1, as indicated by cyan contour lines in Fig. 3 and Supplementary Fig. S3 and as summarized in Supplementary Fig. S2b. Similarly, the value of $L_x/\lambda_{\eta/2}$ is smaller than 0.86 (red dashed line Supplementary Fig. S2c) for only ISWs #1, #2, #3, and #5. If a lenient criterion of $L_x/\lambda_{\eta/2} = 0.8$ (blue dashed line; ref. ⁴²) is taken, the conclusion is the same. Indeed, ISWs #1, #2, #3, and #5 have relatively smooth waveform in comparison with the other ISWs, suggesting the absence of KH instability.

Convective breaking. Unlike shear instability, the convective instability grows primarily within the wave core^{48,56,57}, where the stratification is very weak. Previous observations^{6,47} and numerical simulations^{33,46,56,57} have indicated the convective breaking limit of ISWs was reached as they shoaled. During the upslope propagation of an initial wave at which $U_{\max} < C$, the wave propagation speed decreased successively whereas the particle velocity remained a constant value, and ultimately met the breaking regime $U_{\max} > C$. In summary, four stages of wave evolution were recognized according to those previous studies: (1) an asymmetric waveform characterized by a gentle sloping front edge and

Fig. 3 Competition between shear and stratification. Contours of S^2 (first column), N^2 (second column) and S^2/N^2 (third column) for ISW #4 (first row), ISW #7 (second row), ISW #8 (third row) and ISW #11 (fourth row). The black contour lines are the isotherms from 12 to 29 °C with an interval of 0.5 °C. The magenta contour line is the 18 °C isotherm. The yellow and cyan curves are the contours of $Ri = 0.25$ and $Ri = 0.1$, respectively. The time axis is relative to the arrival time of the ISWs (see “Methods” for details).

steepening at the rear edge as the shoaling waves adjust to the new depth, (2) formation of overturning (heavy-over-light fluid) evolved from the asymmetric waveform, (3) plunging of the heavier fluid into the wave core from the steepening rear edge, and (4) trapped core formed as an enclosed isopycnal region containing heavier fluid. Here, as indicated in Fig. 1d, all of the observed ISWs reach the condition of convective breaking $U_{\max} > C$. Except for ISW #1, our observed ISWs have a waveform similar to the feature of Stage 1, i.e., the gentle front edge and steepening trailing edge in response to the shoaling. Distinct features of convective instability resembling to Stages 2 and 3 are seen in ISWs #1, #7, and #13. ISWs #1 (Supplementary Fig. S1a) and #13 (Supplementary Fig. S1g) show cold-water plunging from the rear edge of wave core as highlighted by the isotherms of 25–29 °C with an interval of 0.1 °C (cyan contour lines). The ISW #7 (Fig. 2b) shows a convective roll-like pair, pointing to an event of colder water injection into the wave core as well, which is referred to Stage 3 and is highly coincident with previous numerical simulations (Fig. 7c in ref. ⁵⁶, and Fig. 7c in ref. ³³). The ISW #11, which is the largest amplitude wave (125 m), reveals a fully developed convective instability within its core (Fig. 2d). It shows warm water near the surface plunging down to ~100 m in the front part of the wave and then rolling up near the trough, while a region of well-mixed water develops at the rear, resembling a large convective overturning (Stage 4). The observed

scene is consistent with simulated fully developed convective instability (Fig. 7d in ref. ⁵⁶ and Fig. 7d in ref. ³³). In ISW #11, the region containing vertically well-mixed water at the rear may be the “trapped core” as described in previous studies, but the core structure is relatively unclear, which may be smeared by the KH instabilities as some billow-like structures can be seen in the rear edge of the wave. The presence of billows in the rear of the ISW #11 can be seen in the echo sounder image as shown in Fig. 4a, c. Otherwise, N^2 computed from the VMP casts prior to the arrival time of ISW #11 showed a very strong stratification ($>1 \times 10^{-3} \text{ s}^{-2}$) in the upper 30 m (Supplementary Fig. S4). The result supports the previous argument that upper layer must be inhomogeneous for the occurrences of convective instability^{58,59}.

The interplay between the convective and shear instabilities. All the observed ISWs reached the condition of convective breaking $U_{\max} > C$, but only four of them revealed the remarkable features of convective overturning in the wave core. The intermittence of the convective overturning can be the cause. To speculate further, the waveform breaking in the trailing edge as a result of the collapse of KH billows may hinder the process of the plunging of cold-water and consequent formation of trapped core by stirring the interface between cold and warm water. Hence, the shear instability could potentially suppress the occurrences of convective

Fig. 4 Shipboard observations of velocity and turbulence. **a, b** UVMP microstructure profiling superimposed on a simultaneous echo sounder image and zonal velocity for the first survey of ISW #11. **c** Echo sounder image for the second survey. **d, e** UVMP microstructure profiling with the background of simultaneous echo sounder image and zonal velocity for the third survey. Black contour lines in **b** and **e** are the isotachs ranging from -1.6 m s^{-1} to 1.6 m s^{-1} with an interval of 0.2 m s^{-1} . A positive zonal velocity is to the east. Thick black contour lines and magenta contour lines in **b** and **e** are the 0 m s^{-1} isotach and -0.4 m s^{-1} isotach, respectively. The wave shown in **a-c** (first survey) propagates to the left. The wave shown in **d-e** propagates to the right.

instability. This point of view hasn't been noticed in the previous studies and needs to be further demonstrated. By contrast, it is well known that the convective instability could enhance the occurrences of shear instability^{37,38,45}. Mixing induced by the convective overturning in the wave core (or upper water column) enhances isopycnal compression, which strengthens the stratification (N^2) and shear (S^2) simultaneously between the core and the pycnocline. However, the strengthening of S^2 is an order larger than N^2 in response to the decrease of dz due to isopycnal compression (see "Methods" for the calculation of S^2 and N^2), in favor of the occurrences of shear instability. Our observations mostly support the above argument as the enhanced S^2 is generally found to be stronger along the lower periphery of the wave core and stronger N^2 is located predominantly below the periphery of the wave core (Fig. 3). The prevailing region where $Ri < 0.25$ is primarily between the core and the thermocline, which supports the findings in ref. ^{37,38,45}. Taken together, these results suggest a scenario of the occurrences of wave instabilities. As an ISW shoals onto the continental slope, convective instability occurred as the wave rear steepened and the trough decelerated in response to the shallower depth. Formation of the convective overturning compressed the isopycnal between the core and the thermocline within

the ISW, where the occurrences of KH instability were enhanced. As these previous numerical simulations and water tank experiments have suggested the occurrences of KH instability do not require the presence of shoaling topography^{39–42}, our observations suggest that the shoaling topography may enhance the KH instability and subsequent turbulence by focusing both the shear and the stratification at the bottom of the wave.

Wave evolution and turbulence. The largest wave ISW #11 was tracked and measured three times until it reached the Dongsha Atoll (Methods). The echo sounder images taken in the first two surveys (Fig. 4a, c) show similar features with those taken by the moored thermistor chain (Fig. 2d), i.e., the plunging tongue in the wave front and the KH billow train (tilted S-shaped band⁶⁰) adjacent to the wave trough. The strong echo as a result of flow instability is primarily in the region of strong westward current as enclosed by the -0.4 m s^{-1} isotach (magenta curve in Fig. 4b, e). The 0 m s^{-1} isotach (thick black curve) well characterizes the depressed waveform. Within the ISW, the maximum current speed of 1.6 m s^{-1} is larger than its wave speed 1.35 m s^{-1} , which favors the onset of convective instability. Before the arrival of the ISW (Fig. 4a), the turbulence kinetic energy (TKE) dissipation ϵ

was $O(10^{-9}-10^{-7}) \text{ W kg}^{-1}$, which are commonly observed values in the open ocean. Cast 4 sliced through the range of the plunging tongue and KH billow train, revealing $\bar{\varepsilon} = 2 \times 10^{-7} \text{ W kg}^{-1}$ and $\bar{\varepsilon} = 4.5 \times 10^{-6} \text{ W kg}^{-1}$, respectively, in their nearby regions. Cast 5 captures a greater range of the plunging tongue (40–110 m), where $\bar{\varepsilon} = 2.2 \times 10^{-6} \text{ W kg}^{-1}$, while $\bar{\varepsilon} = 3 \times 10^{-5} \text{ W kg}^{-1}$ in the KH billows (127–137 m). Casts 6 and 7 were taken within the well-mixed rear as a result of the combination of waveform collapse and convective instability (Figs. 4a and 2d). The well-mixed rear has a mean ε of $2.3 \times 10^{-5} \text{ W kg}^{-1}$ and has a maximum value of $1.7 \times 10^{-4} \text{ W kg}^{-1}$ adjacent to the strong echo band. During the third survey (Methods), the ISW was shoaling up an abrupt slope, where the bottom rapidly rose $\sim 100 \text{ m}$ (Fig. 4d). The waveform depicted by the echogram is drastically distorted due to the shoaling. In contrast, the westward zonal current structure retained its similarity with the measured zonal velocity from the previous survey as shown by the -0.4 m s^{-1} isotach (magenta curves in Fig. 4b, e), but the maximum zonal current velocity decreased to 0.8 m s^{-1} . The eastward zonal currents in the lower layer appear to be squeezed between the westward velocity above and the rising bottom (Fig. 4e), forming a jet-like layer. Measurements taken in the front part of the wave revealed a higher value of $1 \times 10^{-6} \text{ W kg}^{-1}$ around 160 m in cast 5. Within the wave rear, which strongly interacts with the sloping bottom, distinct KH billows with an amplitude of 20–30 m were seen $\sim 20 \text{ m}$ above the bottom. The strong turbulence of $\varepsilon \sim 10^{-5}-10^{-4} \text{ W kg}^{-1}$ is predominant within the KH billows and their upper region, where the convective breaking may be dominant. The strongest ε is $1.4 \times 10^{-3} \text{ W kg}^{-1}$ as shown in Cast 8.

Discussion

Shoaling internal solitary waves can transport and mix cold and nutrient-rich water beneath the thermocline into shallow water and coastal regions^{18,61,62}. The mechanism has been found to change water properties, influence the metabolism of benthic communities, and shape the resilience of coastal ecosystems such as coral reefs^{19,20,63}. The Dongsha Atoll, a Taiwanese National Park and the largest aggregation of coral reef in the northern SCS, is located in the prevailing path of the large ISWs analyzed here. In order to understand the influence of ISWs on biological functioning or potential resilience of reefs, we need to quantify mixing and understand the physical processes leading to turbulence within shoaling internal waves and the transport of sub-thermocline waters to these shallow ecosystems. Distributions of the eddy diffusivity⁶⁴ $K_p = 0.2\varepsilon N^{-2}$ before and during the passage of ISW #11 are shown in Fig. 5. The criterion for the occurrences of shear instability^{45,46} $S^2/N^2 = 4$ clearly distinguishes the distributions of K_p as a function of S^2/N^2 as is shown in Fig. 5a (black line). About 82% of the measurements fall in the stable state ($S^2/N^2 < 4$) with a wide range of K_p from 10^{-6} to $10^0 \text{ m}^2 \text{ s}^{-1}$. Only 18% of our measurements reach the instability condition $S^2/N^2 > 4$, but the value of K_p is generally elevated. It seems that the Miles and Howard's criterion remains applicable. The criterion of the shear instability applicable to ISW instability $S^2/N^2 > 10$ (red dashed line) derived from numerical simulation³⁸ further concentrates K_p on a range of high values 10^{-2} to $10^0 \text{ m}^2 \text{ s}^{-1}$ as highlighted by the gray shading. The gray shading band ($K_p \sim 10^{-2}-10^0 \text{ m}^2 \text{ s}^{-1}$) also includes a region of $S^2/N^2 < 4$, suggesting the absence of shear instability, which is expected to be related to the convective breaking primarily occurring in the wave core where the shear and stratification (Fig. 5a) are weak and the westward currents are strong (Fig. 5b). The mean value of K_p ($10^{-1} \text{ m}^2 \text{ s}^{-1}$) in the shaded band is close to previous measurements within an ISW^{6,37,47} and four orders larger than the common value found in the open ocean⁷ ($10^{-5} \text{ m}^2 \text{ s}^{-1}$) away from

topography and in the absence of ISWs. Finally, the estimated maximal K_p here is 3–4 orders of magnitude higher than the maximum value possible in the K-Profile Parameterization scheme⁶⁵ commonly used in numerical ocean models.

Methods

Mooring instrument observations. To investigate the small-scale processes as ISWs shoal, two moorings A1 and T1 were deployed $\sim 10 \text{ km}$ east of Dongsha Atoll (as denoted by the red and black dots, respectively, in Fig. 1b), as part of a joint field observation conducted by investigators from Taiwan and the U. S. A1 was located 252 m northeast of T1. The T1–A1 line has an angle of 30° to the east. At A1, a 75-kHz acoustic Doppler current profiler (ADCP) was mounted on the bottom at 321 m depth (dashed vertical line in Fig. 1c). The ADCP resolved currents in segments spanning about 40–300 m in 8-m bins. The sampling interval was 6 s. Mooring T1 was equipped with 58 thermistors and deployed at a 323 m water depth (red vertical line in Fig. 1c). The thermistors were attached to the mooring line distributed with a vertical resolution of 4–5 m spanning 26–270 m (red dots in Fig. 2a and Supplementary Fig. S2a). The rapid sampling rate of 0.1 Hz permitted detailed observations of the thermal structure of internal solitary waves, having a typical time scale of 10–20 min and amplitude of 100–150 m. Here, only the overlap period of the two moorings is considered. Two moorings were simultaneously operational during the period 14 May–22 May 2019, which encompassed the arrivals of a set of 15 ISW packets generated surrounding a spring tide (Fig. 1d). The accuracy of the temperature sensors is 0.002°C . The measuring error of ADCP current velocity is 0.076 m s^{-1} , which is lowered to 0.024 m s^{-1} if the 1-min average is taken (for the calculation of shear).

Mooring data integration during ISW events. The ADCP (A1) and thermistor (T1) mooring are 252 m apart, leading to the time lag of observed ISWs between the two datasets. It is essential to combine the two datasets for further analysis. Depending on the ISW propagation speed, the arrivals of ISW at A1 often lead those at T1 1–3 min. The zonal velocity averaged from 150–250 m (U_m) and temperature averaged from 150 to 250 m (θ_m) were used to defined the arrival time of the 15 ISW events at A1 and T1, respectively. The arrival time of an ISW at A1 (t_A) was obtained as the mean time of the two points in time at the half maximal amplitude of U_m . Likewise, the arrival time of ISW at T1 (t_T) was obtained as the mean time of the two points in time at the half maximal amplitude of θ_m . Hereafter, the time frame of an ISW event at A1 and T1 was relative to (centered at) t_A and t_T (Fig. 2 and Supplementary Fig. S2), respectively, so that the two datasets are comparable by assuming the ISW did not significantly evolve from A1 to T1.

Shipboard observations. The shipboard surveys were performed in the cruise during 18–23 May 2019 onboard the Taiwan's Research Vessel (R/V) *Ocean Researcher III* (OR3). Our observations were primarily taken along $20^\circ 42' \text{N}$, (yellow line in Fig. 1b) perpendicular to the prevailing ISW propagation direction (Fig. 1a), using the combination of shipboard 75 kHz ADCP, 120-kHz echo sounder, and tow-yo turbulence profiler. The ADCP was sampled using 8-m vertical bins and 1-min ensembles averaged over ~ 20 pings. The echo sounder sampled at 0.5 Hz with a vertical resolution of 10^{-2} m . The tow-yo turbulence profiler used was the Vertical Microstructure Profiler-250 (VMP-250) manufactured by Rockland Scientific International Inc. (RSI). The VMP-250 was slack tethered by a thin spectra line spooled from a Teledyne Ocean Science Underway CTD (UCTD) winch for vertically profiling turbulence. The system combining the VMP-250 and UCTD winch has been termed the Underway Vertical Microstructure Profiler (UVMP)⁶⁶. Sensors on the VMP-250 include two shear probes and one fast response thermistor (FP07) to respectively sample microscale velocity shear and temperature gradient at 512 Hz. Here, we only focus on the microscale shear measurements and their resultant estimates of dissipation rate of turbulent kinetic energy. The dissipation rate is defined as $\varepsilon = 7.5\nu u_z^2$, where ν is the molecular viscosity and u_z^2 is mean square microscale velocity shear. ODAS software provided by RSI was used to estimate the TKE dissipation rate. Additionally, a Conductivity–Temperature (CT) sensor is mounted on the nose of UVMP to simultaneously sample conductivity and temperature at 16 Hz.

Estimate of wave speed. As mooring A1 was at 252 m northeast of mooring T1, the arrivals of ISW at A1 often lead those at T1 by 1–3 min, which allows computation of the wave speed estimates. As well, wave speed and direction of the leading ISW are estimated by the current measurements at A1 using the iteration method⁶⁷. The distortion of the waveform in velocities as a result of the beam spreading effect of ADCP measurements was also corrected. Propagation speeds estimated using the iterative method (C_i) and the arrival time between A1 and T1 (C_a) were consistent, mostly within $1-1.5 \text{ m s}^{-1}$. Both the mean C_i and C_a of the 15 measured ISWs are 1.3 m s^{-1} . The mean values of C_i and C_a are in agreement with previous observations⁶⁸, giving an ISW propagation speed of 1.05 m s^{-1} at water depths of 200–300 m north of our mooring sites. Hereafter, the wave speed C , the average of C_i and C_a , is used for the following analyses (blue dots in Fig. 1d).

Fig. 5 Drivers of turbulence within the wave. Scatterplots between S^2/N^2 and $\log_{10}(K_p)$ with colored dots representing **a** N^2 and **b** U , respectively. The black line and red dashed line denote $S^2/N^2 = 4$ and $S^2/N^2 = 10$, respectively.

Calculation of velocity shear and buoyancy frequency. Both the current velocity and temperature data were interpolated to a 4-m by 10-second grid. The velocity shear squared is computed as $S^2 = (\frac{\partial u}{\partial z})^2 + (\frac{\partial v}{\partial z})^2$, where u and v are 1-min averaged zonal and meridional velocity (to reduce the velocity error to 0.024 m s^{-1}), respectively. The buoyancy frequency squared is computed as $N^2 = -\frac{g}{\rho_0} \frac{\partial \rho}{\partial z}$, where ρ is the density and ρ_0 (1025 kg m^{-3}) is a reference density, and g (9.81 m s^{-2}) is the gravitational acceleration. ρ is computed from the equation of state by substituting 1-min averaged temperature and a constant value of salinity (34.5 psu).

Wave chasing. ISW #11 was tracked and measured three times before it reached Dongsha Atoll. In the beginning, the ship waited at $20^\circ 42' \text{N}$, $117^\circ 1.59' \text{E}$ (350-m water depth and 2.89 km east of T1) for the arrival of the ISW from the east (Fig. 1c). When the wave arrived, the ship drifted westward with the surface currents induced by the ISW but kept essential steerage so that the ship heading was to the east, to allow the tow-yo UVMP operation on the back deck. About 40 min later, the ISW passed through the ship since the wave speed ($>1 \text{ m s}^{-1}$) was slightly higher than the drifting speed of ship ($0.4\text{--}1 \text{ m s}^{-1}$). After the ISW's passage, the ship immediately turned around and caught up with the ISW at full speed (~ 10 knots) for the second survey (without UVMP). The ship tracks in which the ISW was detected underwater in the first and second surveys were shown as horizontal blue and red lines in Fig. 1c. For the first two surveys, we define a wave coordinate $x_w(t)$ moving with the ISW (Fig. 4a–c), that is $x_w(t) = x_s(t) - Ct$, where x_s is the ship displacement and C is the wave speed. Ship displacement x_s is determined by GPS. It is noted T1 mooring is nearly centered at the track of the second survey. Therefore, wave speed of 0.92 m s^{-1} (C of ISW #11 in Fig. 1d) was applied for the wave coordinate transformation. The wave speed during the first survey is unknown but is inferred as 1.35 m s^{-1} here, so that the horizontal scale of ISW in the two surveys is nearly consistent (~ 1.4 km as denoted by two vertical dashed lines in Fig. 4a–c). The mean wave speed of ISW #11 estimated using the travel time between the location of the first encounter (western end of the blue line in Fig. 1c) and T1 is 1.22 m s^{-1} , a value between 0.92 and 1.35 m s^{-1} in support of our inference. Having transited westward across the ISW #11 for the second survey, we stopped ahead of the wave for the third survey and allowed it to pass the ship to perform the drifting tow-yo UCTD profiling as was done during the first survey. The ship was drifting upslope (westward), advected by the ISW-induced surface current during the passage of the ISW. We did not try to apply the wave coordinate transformation to the third survey because the wave speed here changed rapidly. Seven turbulence profiles, numbered from 1 to 7 in Fig. 4a, were taken before the arrival of the ISW (casts 1–3) and during its passage (casts 4–7) during the first survey. Eleven turbulence profiles were obtained, numbered from 1 to 11 in Fig. 4d, during the third survey.

Data availability

We produced Fig. 1a, b using the reflectance (true color) data distributed by NASA Land Processes Distributed Active Archive Center (LP DAAC). The reflectance data can be downloaded from <https://oceancolor.gsfc.nasa.gov>. Bathymetry data (Fig. 1a) can be downloaded from <https://www.ngdc.noaa.gov/mgg/global/etopo2.html>. Data drawn from ship-based and moored measurements used to produce the figures presented in this article can be obtained from Zenodo repository⁶⁹ (<https://doi.org/10.5281/zenodo.4289412>).

Code availability

ODAS software (MATLAB code) used to estimate the TKE dissipation rate is available from RSI upon request. The code for ADCP data processing can be freely obtained at <https://www.eoas.ubc.ca/~rich/#RDADCP>. Custom codes used for analyses in this article can be obtained upon reasonable request to the corresponding author.

Author contributions

M.-H.C., Y.J.Y., S.J., S.R.R., D.B.R., and K.A.D. designed the field experiment. Y.J.Y., S.R.R., D.B.R., and H.-J.S. performed the field observations. Y.-H.C. and W.-T.H. helped the preparations of the moorings and UVMP profiling. H.-J.S. and R.-S.T. technically supported the VMP profiling. D.S.K. provided the model prediction needed for the field work. M.-H.C. and Y.-H.C. analyzed the data and performed relevant figures. M.-H.C. provided the fundamental idea for interpreting the data and wrote the initial draft. All authors contributed to the data interpretation and writing of the final version of the paper.
