

Evidence for an extensive ice shelf in northern Baffin Bay during the Last Glacial Maximum

Pierre-Olivier Couette^{1,2✉}, Patrick Lajeunesse¹, Jean-François Ghienne², Boris Dorschel³, Catalina Gebhardt³, Dierk Hebbeln⁴ & Etienne Brouard^{5,6}

The glaciological significance of ice shelves is relatively well established for the stability of modern ice sheets of Antarctica. Past ice shelves of the Arctic, however, are poorly documented while their role for the stability of former ice sheets remains mostly unknown. Here we present swath bathymetry data and seismostratigraphic profiles that reveal a large moraine system extending along the continental slope off Baffin Island, demonstrating that a 500-m thick ice shelf covered northern Baffin Bay during the last glacial episode. We suggest that this ice shelf had a profound impact on the stability of a series of major ice streams that drained the interior of the Laurentide, Innuitian and Greenland ice sheets. Climate warming and global sea-level rise in the early stage of deglaciation possibly contributed to a large-scale break-up of the ice shelf, which led to the destabilisation and reorganisation of tributary ice streams from these three ice sheets.

Ice shelves are critical components of marine-terminating ice sheets due to their buttressing effect that controls mass balance by stabilizing the ice margins facing the ocean^{1–7}. Retreat and break-up of ice shelves in Antarctica^{2,3,6,8–11} occur today at a time of important climate warming and may lead to a drawdown of the West Antarctic Ice Sheet, resulting in a rapid transfer of ice to the ocean and thereby contributing to global sea-level rise^{1,2,11,12}. Identifying former ice shelves and reconstructing their evolution through time—particularly for past ice sheets of the Northern Hemisphere where they remain poorly documented^{3,12,13}—will provide an essential analogue for understanding the stability of modern ice sheets and their interplay with climate and global sea-level change.

Baffin Bay forms a 450-km-wide and 2000-m-deep embayment between the Canadian Arctic Archipelago and Greenland (Fig. 1). At the Last Glacial Maximum (LGM; locally ~25–16 ka BP), Baffin Bay was located at the confluence of three ice sheets—the Laurentide (LIS), Innuitian (IIS) and Greenland (GrIS) ice sheets^{14–17}—forming a continuous belt of ice streams draining the interior of Northern North America and Greenland and extending at or near the continental shelf break in many sectors^{18–26}. However, the extension of these ice sheets beyond their grounding zones to form floating ice shelves remains elusive. The scenario of ice shelves in the northern Hemisphere have been hypothesized repeatedly since it was first introduced by Mercer²⁷ as a comparison between the Arctic Ocean and West Antarctica. Hughes et al.²⁸ later expanded the idea to include floating ice shelves in Baffin Bay and eastern North America. The scenario of an ice shelf extending in Baffin Bay from a southern source of ice grounded in Davis Strait and associated with the Hudson Strait Ice Stream was speculated by Hulbe²⁹ as a starting point to explain the mechanisms behind Heinrich events. Although Hulbe et al.³⁰ modified their original stance to instead support fringing ice shelves along the coasts of Eastern Canada, the idea of an

extensive ice shelf sealing Baffin Bay from the Labrador Sea was adopted in the following decades^{31,32}, but this is still debated as a trigger mechanism for Heinrich events³³. However, this scenario was recently refuted by Jennings et al.³⁴ who argued that such an ice shelf would have impeded Labrador Sea water advection, a key component for biological productivity observed at the LGM in cores off western Greenland. They suggested instead that the GrIS margin was protected by either a belt of fringing ice shelves and/or perennial sea-ice—a scenario in line with Hulbe et al.³⁰—that prevented deposition of ice-rafted debris (IRD) and enabled marine advection and food supply during the LGM. Alternatively, a scenario of an ice shelf from a northern source of ice grounded in northern Baffin Bay has been so far unaddressed, in a context where the marine-terminating Lancaster Sound and Smith Sound ice streams captured several major tributaries from the LIS, IIS and GrIS^{17,21}, creating ideal conditions for the formation of an ice shelf that potentially controlled the stability of other ice streams outflowing from the eastern Canadian Arctic Archipelago and western Greenland^{17,24,25}.

Solving the ice shelf issue in Baffin Bay is therefore necessary for evaluating the effects of buttressing on ice flow, ice streams stability and ice sheet mass balance changes during a key stage of deglaciation of the Arctic and a period of major meltwater flow into the ocean. Here we present geophysical (swath bathymetry, acoustic profiles) datasets and a compilation of previously published sediment core data collected on the outer sector of the cross-shelf trough off Clyde Inlet (Baffin Island) and its adjacent continental slope of western Baffin Bay that together demonstrate the existence of an ice shelf in northern Baffin Bay—the Northern Baffin Bay Ice Shelf (NBBIS)—during the last glacial episode (Fig. 1). This geomorphological evidence and the re-interpretation of sediment cores allow defining the extent of the LIS on the continental shelf at the LGM and examining the potential impact of an ice shelf collapse on the evolution of ice streams of the three marine-terminating ice sheets in Baffin Bay.

Results and discussion

The geomorphological signature of the NBBIS. Three ridges running in parallel to the continental slope off Clyde Trough between 300 and 420 m below sea-level (mbsl) are observed on the swath bathymetry imagery (Fig. 2a, b). These ridges are independent from grounding zone wedges (GZWs) constructed by outlet glaciers and ice streams emanating from Baffin Island. The central ridge is the largest; it is 30-m high, ~300-m wide and extends almost continuously for >30 km along the slope off Clyde Trough (Figs. 2a and 3). It has an asymmetric profile showing a gentler ocean-facing slope and is observed at progressively decreasing depths from north (330 mbsl) to south (300 mbsl). Although it appears to be streamlined along the continental slope, one of the segments of the central ridge (Fig. 2b and c) shows evidence of sediment accretion by ice push in a NW-SE direction (i.e., towards Baffin Island). In addition, two 5–10 m-high subdued ridges occur on both sides of the main ridge at 420 and 310 mbsl, extending for <5 km in front of Clyde Trough and showing geomorphic similarities to the neighbouring central ridge (Fig. 2b). Similar ridges are also observed at 350 mbsl off Sam Ford Trough and 410 mbsl south of Scott Trough, 40 and 100 km northwest of Clyde Trough, respectively (Fig. 4). These ridges probably correspond to the central ridge observed on the upper continental slope off Clyde Trough as they are also ~30 m high with a gentler ocean-facing slope.

We rule out the possibility of these landforms being terminal moraines of the LIS on the upper continental slope as its geometry does not appear to be influenced by the location of cross-shelf troughs. If they indeed originated from flowing ice

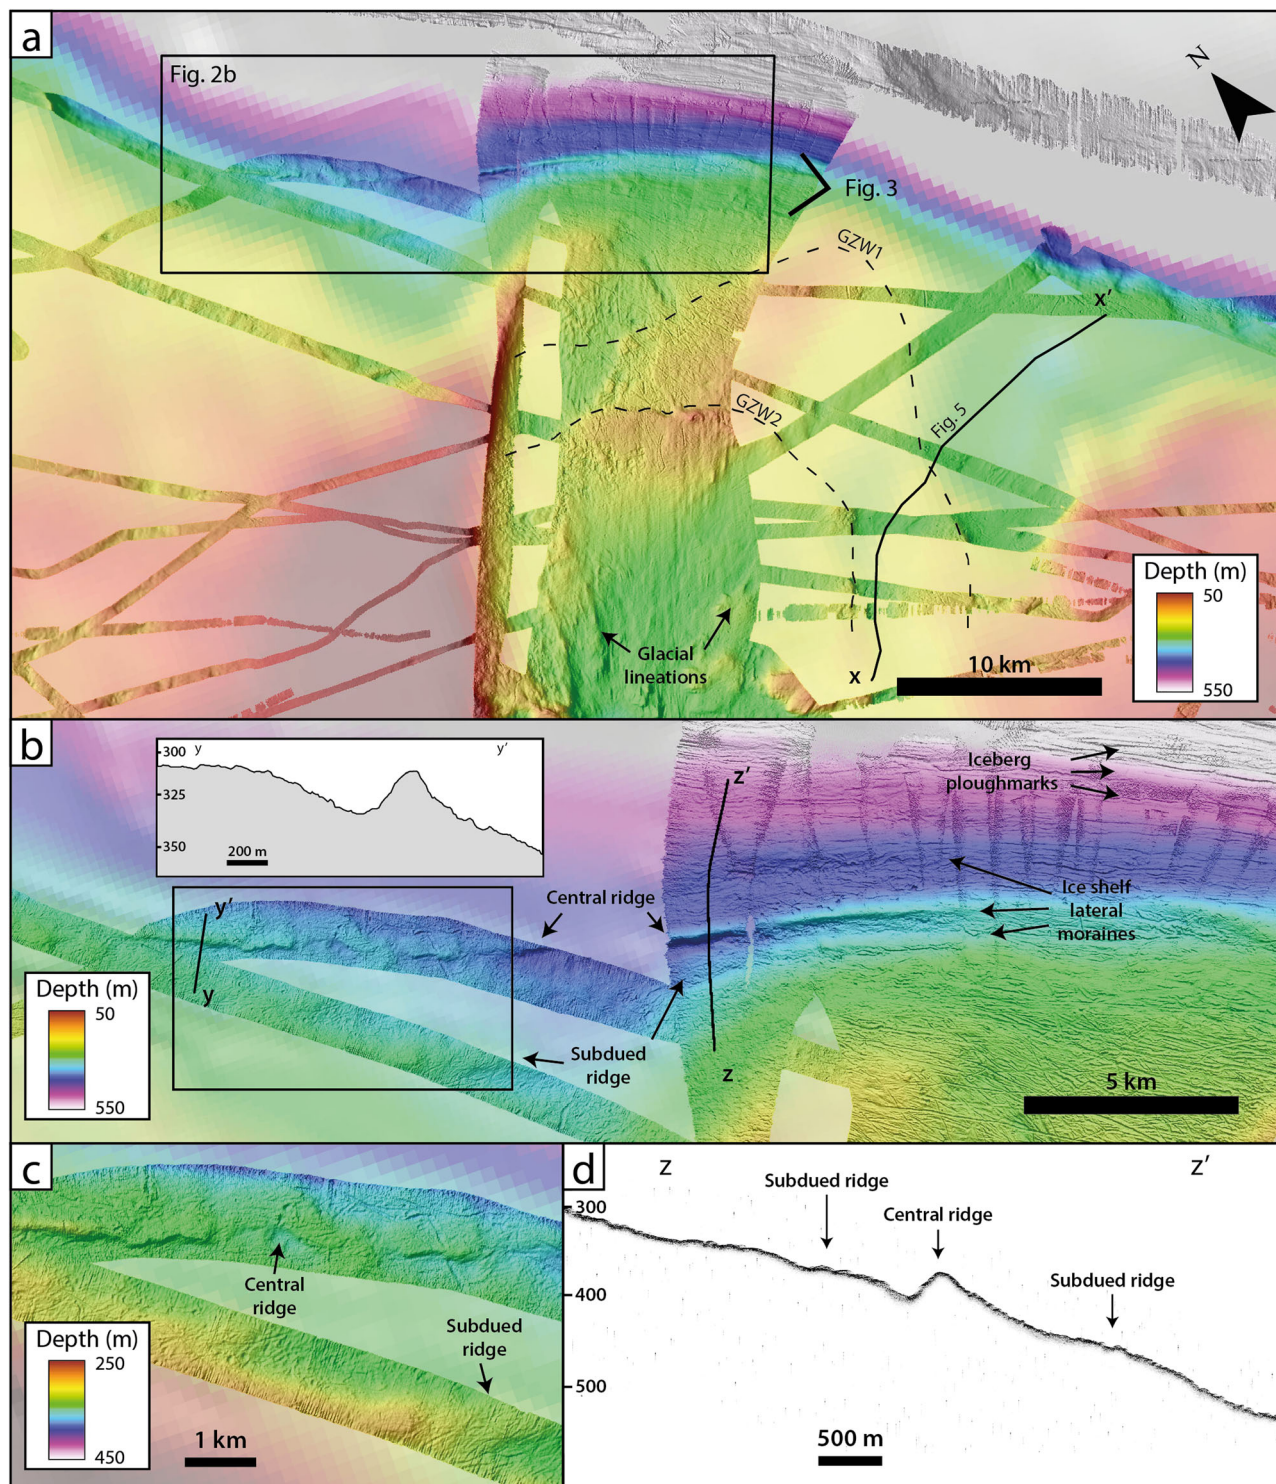

Fig. 2 Geophysical data along the Baffin Shelf margin off Clyde Trough. **a** Bathymetry of the outer Clyde Trough and adjacent upper continental slope (see Fig. 1). across the Baffin Island continental shelf, a bulge should be expected in front of the trough. Instead, we observe a curvature in the orientation of these ridges into Clyde Trough (Fig. 2a). These ridges are therefore interpreted as lateral moraines of the NBBIS on the basis of (a) their geomorphology similar to previously reported ice-shelf moraines in the Canadian Arctic Archipelago^{35–40}, and (b) their location, depth and orientation

along the continental slope off Baffin Island. The progressively decreasing depths of these ice shelf lateral moraines comply with a paleoglaciological reconstruction including a seaward thinning of the ice shelf. The smaller ridges could represent different phases and/or thickness changes of the NBBIS during the LGM, although their relatively subdued appearance could also suggest their formation during prior glaciations (i.e., MIS-6).

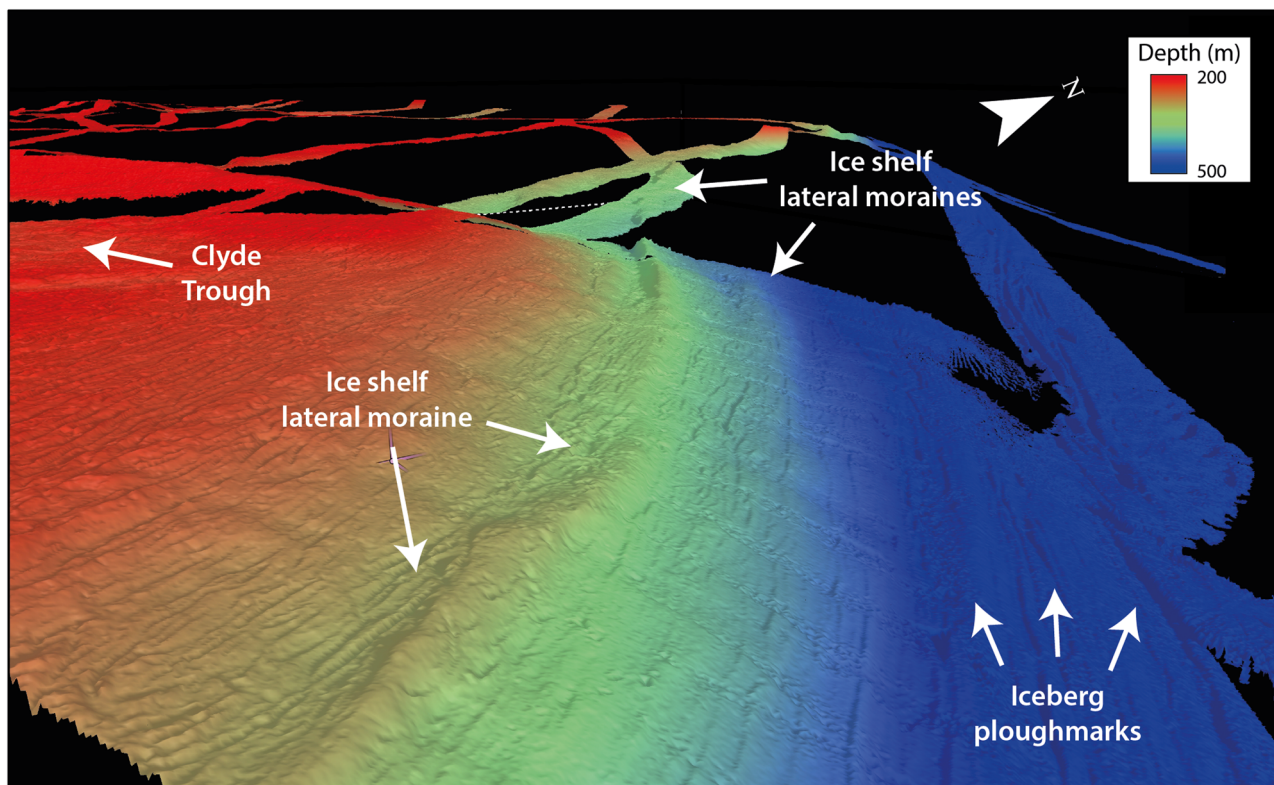

Fig. 3 The ice shelf lateral moraines on the continental slope off Clyde Trough. 3D imagery generated using the QPS Fledermaus software showing the ice shelf lateral moraines and iceberg ploughmarks.

In outer Clyde Trough (Figs. 2a and 3), the absence of gullies on the trough-mouth fan and of streamlined glacial bedforms at the continental shelf edge suggest that the Clyde Ice Stream (CIS) did not reach the continental shelf break at the LGM—in contrast with other ice streams on northeastern Baffin Island²⁵—and was probably not connected to the NBBIS. This disconnection between the CIS and the NBBIS in outer Clyde Trough is supported by the presence of two GZWs located ~10 km landward from the continental shelf edge and ~15 km west of the slope ridge system (Figs. 2a and 5), leaving an open area between the CIS margin in the outer trough and the grounded NBBIS on the slope.

More to the north, a GZW located ~20 km off Scott Trough at ~450 mbsl and associated with streamlined bedforms oriented parallel to the continental slope indicate grounded ice flowing southeastward along the shelf (Figs. 4a and b). The streamlined bedforms are similar to mega-scale glacial lineations^{41–43} or sub-ice shelf keel scours^{6,44} and were recognized to be the product of ploughing across the seafloor by an ice shelf. This system therefore suggests that ice flowing out of the Scott Trough was either (1) deflected from its along-trough original flow by an obstacle (i.e., a floating ice shelf in Baffin Bay); or (2) a large independent ice body expanding all the way up to Clyde Trough (i.e., a fringing ice shelf). The first hypothesis is more probable as there is no explanation for the divergence of the Scott Ice Stream from an along-trough to along-slope orientation without a buttressing mechanism. These landforms, together with the ice shelf lateral moraines observed at shallower depths than the bottom of Scott Trough (>600 mbsl; Supplementary Fig. 1), suggest that, in contrast to Clyde Trough, the Scott Ice Stream—and probably other systems of northeastern Baffin Island—merged with the NBBIS. Mega-scale glacial lineations, ice stream lateral moraine and ‘lift-off’ moraines identified by Brouard and Lajeunesse²⁵ on the Scott trough-mouth fan in turn indicate an

ice streaming phase extending to the shelf edge (Fig. 4a). Initially interpreted as features of LGM ages²⁵, they could instead correspond to a local subsequent readvance prior to 14.2 kyr BP⁴⁵.

In addition, the continental slope along Baffin Island is heavily affected by curvilinear scours between 5 and 10 m deep and down to >750 mbsl (Figs. 2a, 3 and 4a). These scours, interpreted as iceberg ploughmarks, indicate extensive calving from a thicker body of ice in northern Baffin Bay probably after the LGM¹⁵.

The available swath bathymetry and seismostratigraphic data do not allow identifying ice shelf lateral moraines south of Clyde Trough with confidence and, therefore, precisely addressing the NBBIS extent toward southern Baffin Bay. Faint bedforms similar to those presented above are observed on the bathymetry some 120 km to the south, but their association with those off Clyde Trough is ambiguous as they are located at greater depths (~400 mbsl; Supplementary Fig. 2). The timing of formation of this ice shelf lateral moraine is also unknown as no sediment core, thus no direct dating, were retrieved on this bedform. In this context, the presence of an extensive ice shelf on the Arctic ocean during MIS-6^{42,46} could suggest contemporaneity on Baffin Bay. Such an ice shelf is supported by a raised marine sediment sequence identified on Eastern Baffin Island^{47,48} that was dated at this period⁴⁹, suggesting a more extensive ice cover during the penultimate glaciation. In addition, several studies provided evidence for the presence of the LIS along the eastern margin of Baffin Island throughout MIS-4 to MIS-2^{50–55}. However, sediment records in Baffin Bay and along the Baffin Island continental shelf allow discussing the potential timing and extent of the NBBIS.

The sedimentary signature of the NBBIS. The previously published sediment records from Baffin Bay (Fig. 6)^{14,21,45,56–60} are compatible with the presence of an ice shelf during the LGM. The

buildup of ice sheet prior to the LGM is marked by a layer of IRD and carbonate-rich sediments originated from northern Baffin Bay termed Baffin Bay Detrital Carbonate (BBDC) layer, which is identified basin-wide and dated between 26 and 24.7 kyr BP

(BBDC-245,56,57,60). The quasi-absence of IRD throughout the LGM (~24.7--~16.5 kyr BP) in most cores of Baffin Bay suggests an extensive ice cover, either as perennial sea ice⁶¹ or an ice shelf^{6,34}. The occasional clasts observed in some cores of northern

Baffin Bay could be explained by their relatively short distance from the ice grounding line as it is affected by mass flows and the rain out of ice shelf basal debris^{6,33,62–64}. Provenance study on core 16PC, located 100 km east of Clyde Trough in central Baffin Bay (Fig. 1), shows uniform mineralogic composition dominated by a Greenland-sourced sediment assemblage and a restricted Baffin Island-sourced input during the LGM interval⁵⁷. Localized and uniform mineralogic assemblages are typical of sub-ice shelf setting reflecting uniform conditions in which transport is dominated by meltwater plumes^{6,65}. A coarsening-upward trend with frequent IRD in cores of Baffin Bay starts at ~16.5 kyr BP^{57,58,60} and is followed by the deposition of carbonate-rich BBDC-1 between ~14.5 and ~13.7 kyr BP^{57,60}. Such a coarsening-upward sequence typifies the progressively more open water conditions that usually follow ice shelf collapse events^{6,64}. This sedimentary record is therefore in support to the hypothesis of an ice shelf in Baffin Bay during the LGM. In addition, it provides a temporal framework suggesting that break-up started at ~16.5 kyr BP and ended with the onset of BBDC-1 at ~14.5 kyr BP^{15,57,60}.

Sediment cores collected on the Baffin Island continental slope (Fig. 6) allow defining the position of the LIS margin on the continental shelf off Baffin Island during the LGM and early deglaciation. The base of most cores is marked by ice-proximal dark grey-brown diamicton interpreted as glacial debris-flow deposits and correlated to an ice advance at ~25 kyr BP⁴⁵. In 77PC, a gold brown mud layer located halfway along the core was correlated to BBDC-2^{26,45} and therefore correspond to the ice advance observed in the other cores along the continental slope. Provenance study on this core indicates that a localized source of carbonate sediments, originating from a Paleozoic outcrop east of the Home Bay area^{66,67}, also contributed to the composition of the gold brown mud layer⁶⁸. Cores from the continental slope offshore Baffin Island (Fig. 1) typically consist of laminated red brown mud with rare or absent IRD during the LGM interval. Jenner et al.⁴⁵ noted, however, that coarse IRD-rich beds from the basal diamicton gradually decrease in abundance upwards into laminated red brown mud and very fine sand with IRD in cores 61PC off Scott Trough. These laminated red brown muds are interpreted as lateral sediment supply from NE Baffin Island, as they thin in deeper water off the trough mouth fans^{14,45}, an interpretation corroborated by their mineral composition⁶⁰. They are, however, absent in core 73PC (Fig. 1), suggesting the absence of grounded ice at the shelf break in Clyde Trough during the LGM, in line with the receded position of GZWs and the presence of predominantly Greenland-sourced sediments in core 16PC⁵⁸. Except for 77PC, located off Home Bay in southern Baffin Bay, the laminated red brown muds are characterized by an absence of bioturbation and microfossils⁴⁵. According to the ice-shelf

sedimentary model of Smith et al.⁶, this sequence might represent an ice advance to the continental shelf edge at the LGM (stratified diamicton), followed by ice shelf buildup with frequent iceberg calving (turbidites interbedded with IRD layers) and, ultimately, a full ice shelf cover (laminated red brown mud). A second diamicton overlying the red brown laminated muds is observed immediately below BBDC-1 in cores north of Clyde Trough^{45,69}, representing glacial debris-flow deposits correlated to a smaller localized advance from northeastern Baffin Island ice streams to the shelf break prior to 14.2 kyr BP⁴⁵.

To our knowledge, no sediment core has been collected or published from the Greenland side of northern Baffin Bay to allow direct comparison with Baffin Island continental slope assemblages. In southern Baffin Bay, sediment core data show similar sequence as those from the Baffin Island continental slope^{34,70,71}. However, widespread foraminifera assemblages and bioturbation during the LGM interval suggest the presence of perennial sea-ice⁶¹ and/or a nearby ice shelf margin^{62,72,73}. A thorough discussion on sediment assemblages and their relation to ice shelf and/or perennial sea-ice on the continental slope of western Greenland was provided by Jennings et al.³⁴.

Evidence of ice shelf inception in northern Baffin Bay. The presence of an ice shelf in northern Baffin Bay at the LGM and during the early stage of deglaciation is supported by invoking the Marine Ice Cliff Instability (MICI) theory, which stipulates that fracturing due to longitudinal stresses exceeding the yield strength initiate ice cliff failures when a marine-based ice-margin reaches ~1 km in thickness^{74–76}. Till wedges, GZWs and megascale glacial lineations identified on the upper continental slope off Lancaster Sound^{21,25} and Smith Sound (Supplementary Fig. 2) indicate grounded ice as deep as 1350 mbsl. Accounting for a coeval higher relative sea-level (RSL) of ~75 m based on the modelled RSL values from a nearby Baffin Island site⁷⁷, ice thickness can be estimated using:

$$H_{LGM} = (\rho_w / \rho_i) \cdot (D + \Delta D_{LGM}) \quad (1)$$

where H_{LGM} is the minimum ice thickness during the LGM, $\rho_w = 1028 \text{ kg m}^{-3}$ and $\rho_i = 910 \text{ kg m}^{-3}$ are the mean densities of sea water and ice, respectively, D is the water depth and ΔD_{LGM} is the correction for water depth at the LGM⁷⁴. In the case of the Lancaster Sound and Smith Sound trough-mouth fans, grounded ice had to be >1550-m thick. The Lancaster Sound till wedges and the Smith Sound GZW could not have been deposited without an ice shelf buttressing—and temporarily stabilising—the front of these ice streams^{4,76,78}. In order to maintain a stable position without an ice shelf in northern Baffin Bay, the ice margin would have needed to retreat until it reached the theoretical depth of

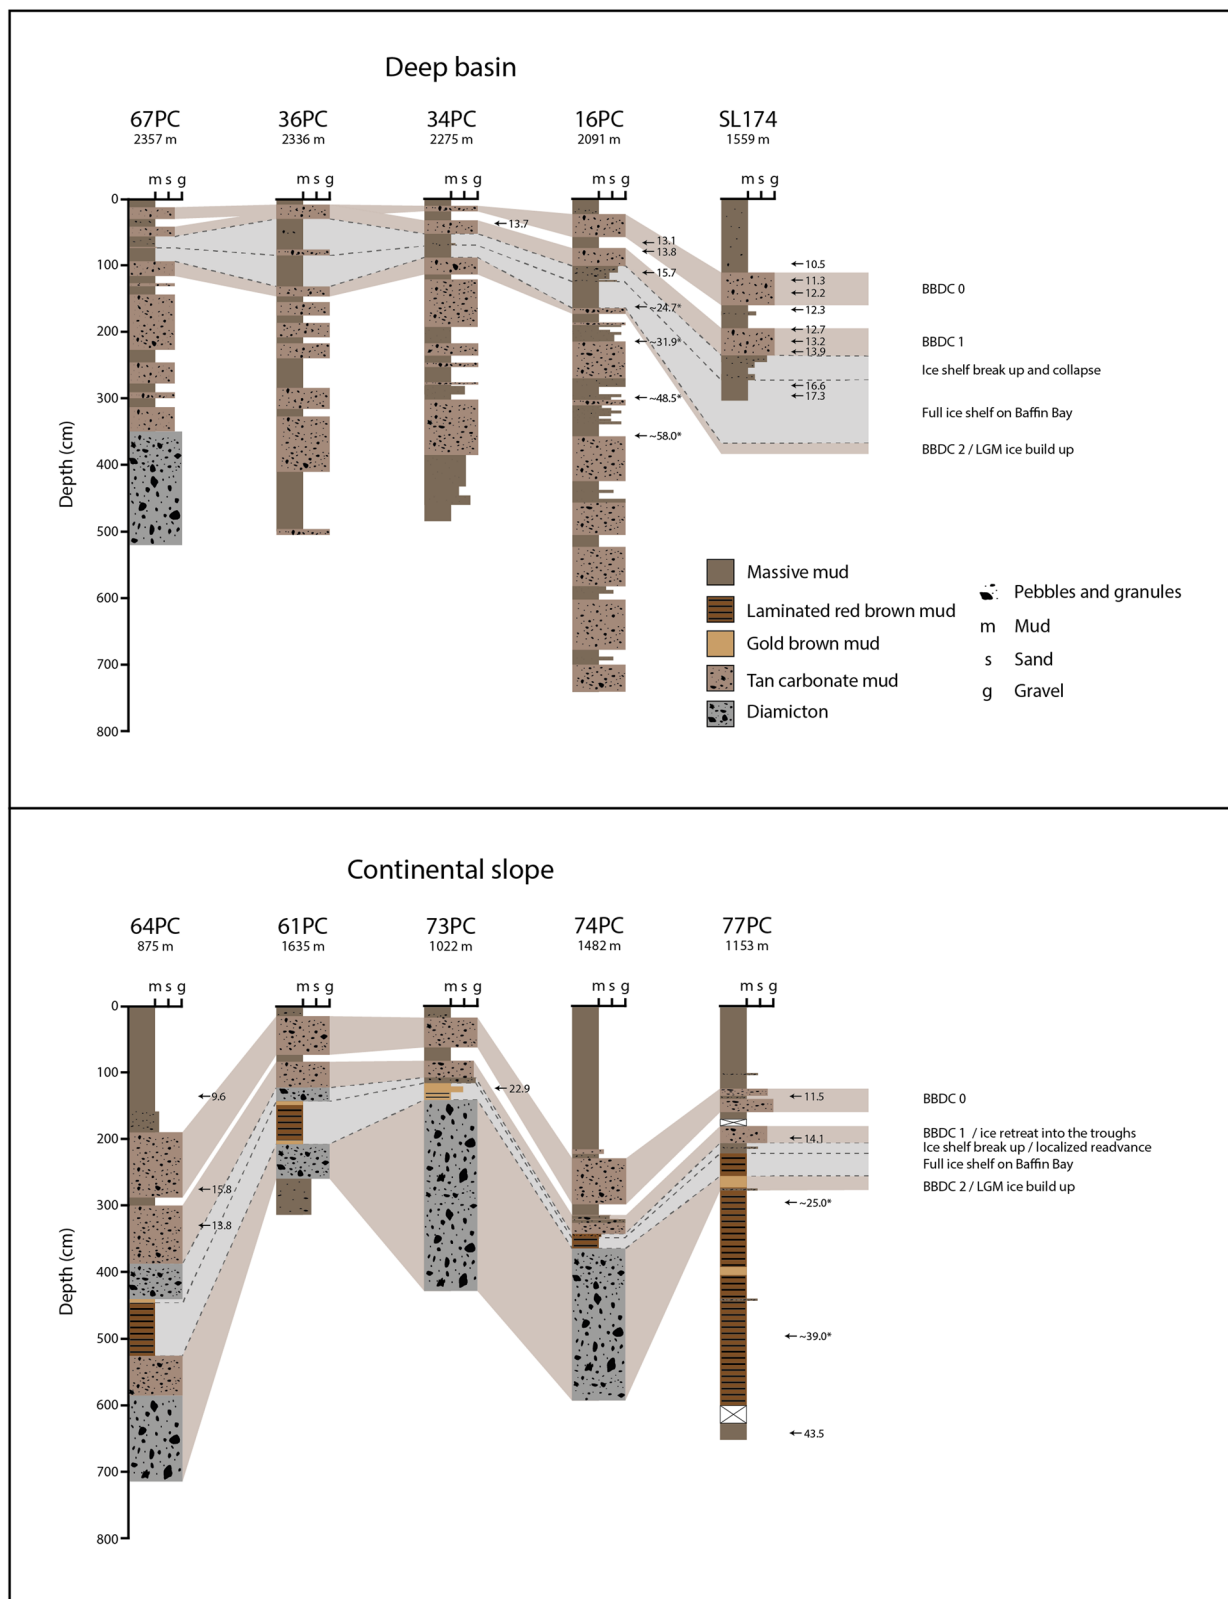

Fig. 6 Sediment assemblages in Baffin Bay and along the Baffin Shelf. Lithology of piston cores from Baffin Bay modified from various published datasets (see 'Methods'). Radiocarbon ages are reinterpreted in calendar years using the online software Calib 8.2 with the Marine20 radiocarbon age calibration curve⁸⁷ and a local reservoir correction (ΔR) of 87 ± 20 ⁸⁸. In addition, relative paleointensity (*) chronology is also presented for core 16PC⁵⁹ and 77PC²⁶. Correlations are based on Baffin Bay detrital carbonate (BBDC) beds and are compiled from original publications. BBDC events are represented by the brown shaded areas—ages are from Simon et al.⁵⁷ and Jackson et al.⁶⁰: BBDC-2: -25–24.7 kyr BP; BBDC-1: -14.2–13.7 kyr BP; BBDC-0: -12.7–11 kyr BP. The grey shaded horizon represents ice shelf setting on Baffin Bay; note the quasi-absence of IRD during that interval.

~800 m, hence continually calving icebergs throughout the LGM⁷⁶. Such a constant calving in northern Baffin Bay is, however, not compatible with the sedimentary record from the slope and deep basin off Baffin Island (Fig. 6) where a quasi-absence of IRD was observed during this interval. Moreover, numerical models indicate that ice grounded at 1500 mbsl is expected to form a ~500-m-thick ice shelf⁷⁹; a thickness consistent with observations off Clyde Trough where ice shelf lateral moraines are observed at ~400 mbsl (i.e., ~475 m at the LGM).

Implications of a NBBIS. Glacial landforms and deposits off the Baffin Island continental shelf combined with the Baffin Bay sedimentary record provide definitive evidence for the presence of a 500-m-thick ice shelf in northern Baffin Bay at and shortly after the LGM. The scenario of an ice shelf fed by ice streams located in northern Baffin Bay does not require grounded ice in Davis Strait sealing inflow of food supply from Labrador Sea waters, therefore reconciling with biological productivity observations on the continental slopes of southern Baffin Bay during the LGM^{34,45}. This scenario provides a framework for revising the glaciation development around Baffin Bay and reassessing the potential impacts of the ice shelf collapse on the reorganisation of major ice streams draining the LIS, IIS and GrIS during the last glacial cycle (Fig. 7).

Ice shelf inception at the LGM. Based on the presence of BBDC-2 and diamicton along the margin of eastern Baffin Island, the NBBIS probably started building up with an advancing ice shelf margin across Baffin Bay between ~26 and ~24.7 kyr BP. The presence of the short-lived BBDC-3 event⁴⁴ suggests an earlier buildup with frequent break-up of the NBBIS margin. This earlier buildup would be in line with the presence of the LIS on the Baffin Island continental shelf—and possibly Lancaster Sound—during MIS-3^{50–55}. An extensive LIS during MIS-3 would likely have facilitated an earlier advance of the ice margin across the other shelves surrounding Baffin Bay. Regardless of the exact timing of ice shelf inception in northern Baffin Bay, grounded ice flowing from Lancaster Sound and Smith Sound fed the NBBIS between at least ~24.7 and ~16.5 kyr BP, which in turn buttressed peripheral glaciers and ice streams of the eastern Canadian Arctic Archipelago and possibly Western Greenland. The available geological record allows identifying the southward extent of the NBBIS at least down to the latitudes of Clyde Trough. The relatively shallow depths of the ice shelf lateral moraine in front of Clyde Inlet (<350 m) suggests that the ice shelf was thinning and its margin was possibly located nearby, therefore making it difficult to extend farther south to Home Bay and preserve a constant thickness of ~500 m for >100 km. Although geophysical data from the Greenland continental shelf do not allow confirmation, it is probable that the ice shelf had a similar extent across the entire Baffin Bay. The relatively deep troughs (<500 mbsl) on the Greenland side of northern Baffin Bay possibly prevented the formation of ice shelf lateral moraines. Similarly to northeastern Baffin Island, ice streams located off the GrIS may have merged with the NBBIS. The exact extent of the NBBIS in southern Baffin Bay remains unknown; sediment assemblages^{45,60} show similarities to those of northern Baffin Bay, while the record of marine productivity during the LGM suggests openings in sea-ice as polynias and/or advection under a proximal ice-shelf margin³⁴. It is therefore possible that, while northern Baffin Bay was covered by a basin-wide ice shelf system, southern Baffin Bay was characterized by fringing ice shelf and/or perennial sea-ice along both continental shelves, which could also explain the presence of ice shelf lateral moraines off Home Bay.

Ice shelf break-up and collapse. Rising sea level and/or enhanced incursion of relatively warm Atlantic waters via the Western Greenland Current^{34,80} may have provoked a destabilization and collapse of the NBBIS front between ~16.5 and ~14.2 kyr BP (Supplementary Fig. 3). The initiation of this break-up is recorded by an increase in IRD and coarse-grained sediments in cores from Baffin Bay^{57,60}. Such a break-up would have been accelerated by warming summer temperatures⁸¹ providing the necessary heat to produce sufficient meltwater to fill crevasses and induce hydrofracturing^{10,11}, in turn favouring the production of small icebergs rather than large tabular icebergs^{1,4,30}. The final collapse of the NBBIS corresponds to the onset of widespread delivery of northern Baffin Bay-sourced detrital carbonates in Baffin Bay—BBDC-1^{15,58,60}.

Ice streams acceleration. As the NBBIS rapidly collapsed by ~14.2 kyr BP, ice streams of northeastern Baffin Island became unbuttressed, thereby thinning due to their acceleration, similarly to observations made on present-day ice shelves in Antarctica^{1,5,7,8}. The accelerated discharge from northeastern Baffin Island ice streams probably led to the deposition of the younger diamicton identified on the continental slope north of Clyde Trough⁴⁵. The MSGs and ice stream lateral moraines at the shelf edge in Buchan and Scott troughs²⁵ further supports this acceleration of ice streams. The presence of 'lift-off' moraines at the shelf break²⁵ suggests tidally related buoyancy at the grounded ice sheet margin⁸², which could potentially be a sign of ice stream thinning. The absence of the second diamicton south of Clyde Trough suggests that no readvance nor glacier acceleration occurred in Clyde Trough, probably because the CIS was not initially buttressed by the NBBIS. The occurrence of ridges similar to 'lift-off' moraines on Melville Bay trough-mouth fans²⁴ could hint to a similar history as for the northeastern Baffin Island ice streams. Ice streams acceleration around northern Baffin Bay are coeval to a period marked by exceptionally high rates of global sea-level rise (Meltwater Pulse 1A^{12,83,84}) suggesting contribution of the North America High Arctic ice sheets to this event.

Ice retreat in cross-shelf troughs. Ice stream fronts retreated landward within their troughs at ~14.2 kyr BP⁴⁵, consistent with previous age constraints of ice retreat from the Baffin Island continental shelf^{19,20,45}. The previous event of ice purge may have resulted in their episodic retreat in northeastern Baffin Island due to their destabilisation²⁵, whereas the initially unbuttressed CIS margin underwent a slower retreat. Furthermore, ice retreat in Lancaster Sound and Smith Sound led to the increased delivery of IRD-rich carbonates and deposition of BBDC-1 in Baffin Bay^{15,45,56–58,60}.

Conclusion

Identifying landforms associated with modern ice shelves remains a challenge due to their scarcity, the difficulty to access sub-ice-shelf environments and technological limitations of sonar imaging systems. However, the last decades witnessed improvements in ship-bound technologies (i.e., high-resolution multibeam echosounder, autonomous underwater vehicle and 2D/3D seismic imagery) allowing the identification of submarine bedforms diagnostic of past ice shelves, such as sub-ice-shelf keel scours/mega-scale glacial lineations^{41–43}, GZWs⁴² and corrugation ridges⁴⁴. A more comprehensive understanding of such landforms is of particular interest as they provide direct and key evidence for past ice shelves in the Arctic, which may have considerable implications on glacial dynamics at the margin of continental ice sheets that was so far little studied.

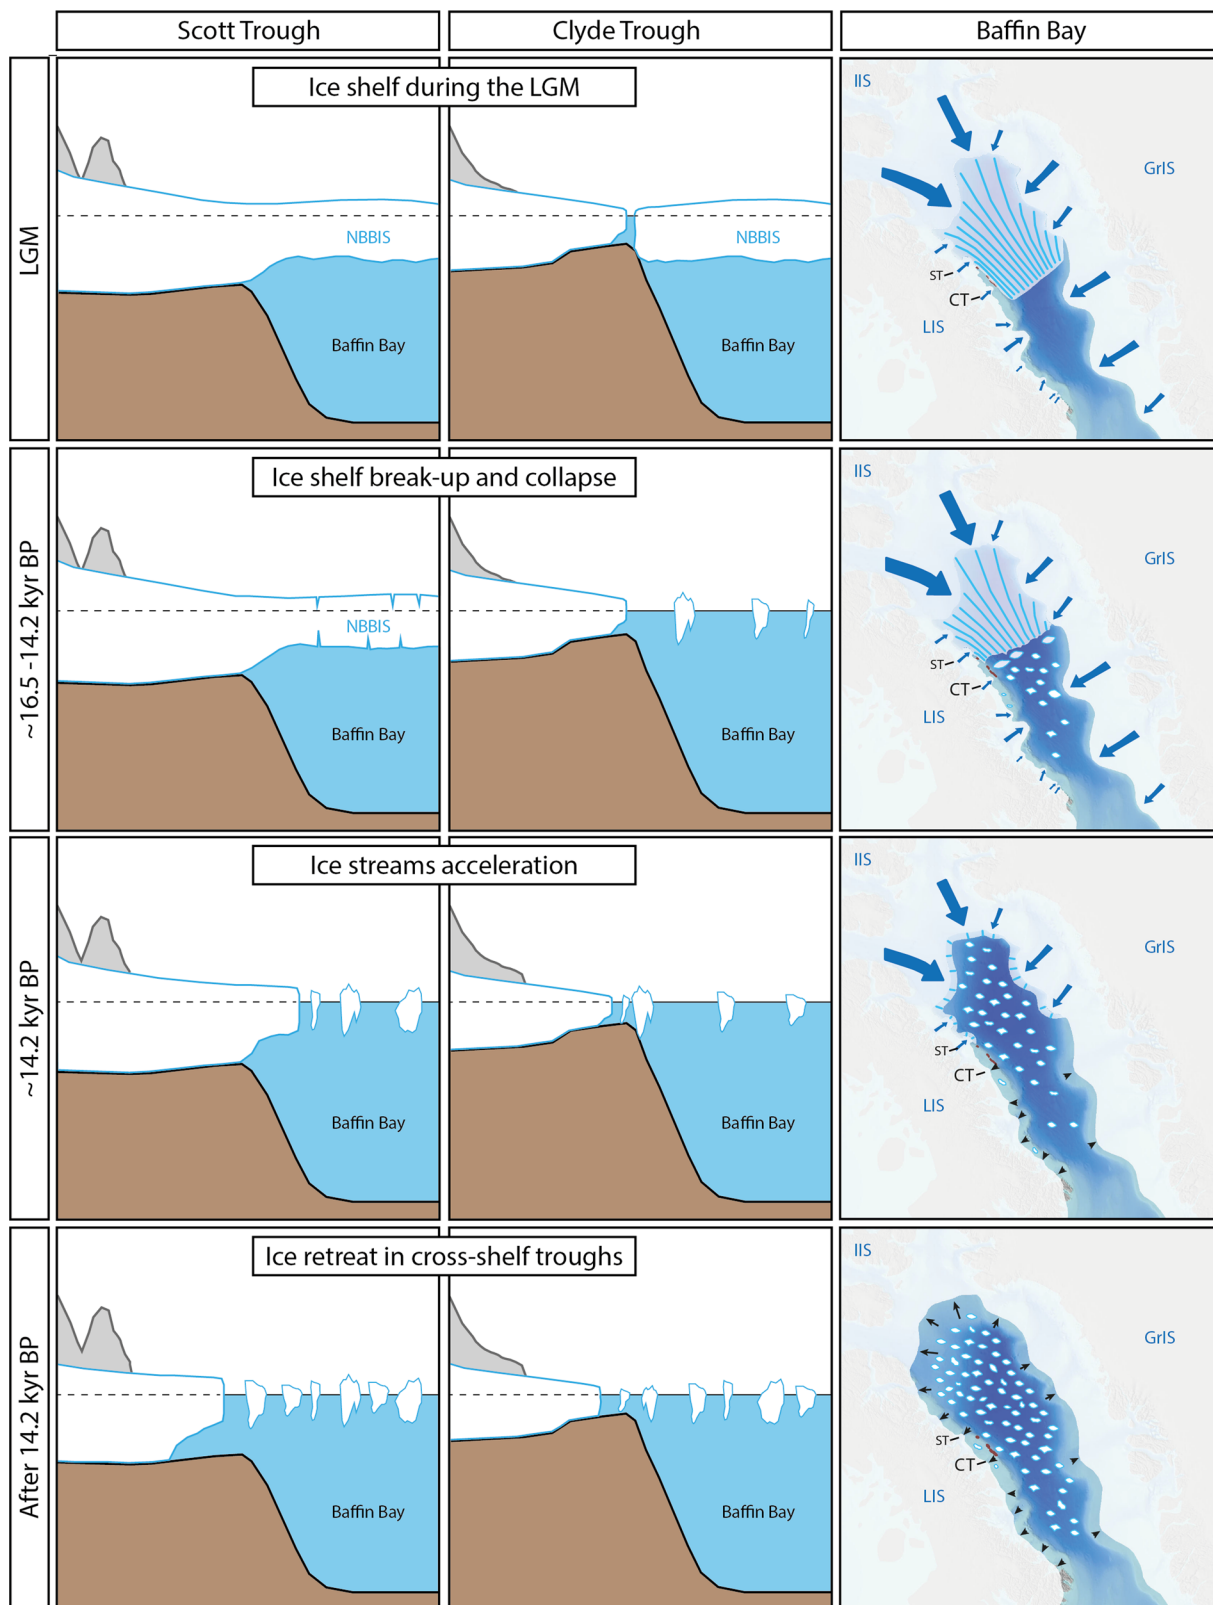

Fig. 7 Conceptual model for early deglaciation including the NBBIS and the LIS outlets in Baffin Bay. Reconstruction of ice sheets in Baffin Bay during the LGM and subsequent deglaciation. LIS Laurentide Ice Sheet; IIS Inuitian Ice Sheet; and GrIS Greenland Ice Sheet. CT Clyde Trough; ST Scott Trough. Blue arrows indicate an advancing or stable ice margin and black triangles indicate a retreating ice margin. Brown lines represent ice shelf lateral moraines along the Baffin Island continental shelf.

The ice shelf scenario in northern Baffin Bay provides a satisfactory explanation for the landforms observed along the continental slope between Scott and Clyde troughs, as well as in Lancaster and Smith sounds. It is also in agreement with sediment assemblages identified on the continental slopes off Baffin Island and Greenland, as well as in Baffin Bay itself during the LGM. With a surface of at least 150,000 km²—an area comparable to some of the largest ice shelves of present-day Antarctica—the NBBIS constitutes an analogue from the past for understanding future changes to the cryosphere in a warming world in a context of disintegration of buttressing ice shelves. The demise of the NBBIS would have provided an ideal setting for triggering the acceleration of ice streams and the rapid loss of glacial ice to the ocean, thereby influencing drastically the ice flow regimes of the LIS, IIS and GrIS. These findings could further support the hypothesis that the North America High Arctic ice sheets did not have considerable contribution to rising sea level before Meltwater Pulse 1A^{83,84}. Defining the extent of the NBBIS and the chronology of its history is, however, necessary for assessing a scenario that should include the acceleration of major Arctic ice streams following ice shelf collapse when identifying sources for Meltwater Pulse 1a. This paper provides the basis for further investigations aiming at documenting—both offshore and onshore—lateral ice shelf moraines of past ice shelves of the Arctic seas.

Methods

Geophysical data along the Baffin Island continental slope. Swath bathymetric data was collected in 2017 during expedition MSM66 of the RV Maria S. Merian⁸⁵ using a Kongsberg Simrad EM122 (12 kHz) system, which allowed the coverage of Clyde Trough. This dataset is complemented by swath bathymetric data from ArcticNet cruises collected during transits from 2003 to 2016 onboard the CCGS Amundsen, equipped with a Kongsberg Simrad EM302 (30 kHz). These datasets were processed for anomalous data points and artefacts removal using Caris Hips and Sips software and gridded at a 10 m cell-size resolution. They were then imported into ESRI ArcGIS software for geomorphological mapping and landforms identification. The International Bathymetric Chart of the Arctic Ocean (IBCAO) data⁸⁶, gridded at a 500 m cell-size resolution, was also used to show overall bathymetry of Baffin Bay and its adjacent shelves. Parasound profiles were acquired onboard the RV Maria S. Merian using a Teledyne-Recon Parasound DS P-70 (secondary low-frequency ca. 4 kHz). The raw data were recorded into ASD and PS3 format and then converted into SEGY using ps32segy software of Dr. Hanno Keil (University of Bremen). The shallow-acoustic profiles were then imported into the IHS Markit Kingdom software for processing and interpretation. Seismic lines 78029_AG_274_1516 and 80028_AG_RAYT_257_0200 were acquired by the Geological Survey of Canada during airgun surveys in 1978 and 1980, respectively. Extraction and interpretation were done using the LizardTech GeoViewer[®] software. Both acoustic and seismic data were then transferred into Adobe Illustrator[®] for figure production. Thicknesses and water depth were calculated using a velocity of 1500 m/s.

Sediment cores and chronology. Sediment cores were compiled from previous studies to describe the lithostratigraphy along the Baffin Island continental slope and in Baffin Bay. Jenner et al.⁴⁵ noted that cores 64PC, 61PC, 74PC and 77PC (all included in this study) typify the regional lithostratigraphy along the northeast Baffin margin from north to south. In addition, core 73PC⁴⁵ was included in the compilation as it was located nearby Clyde Trough. Cores located directly in front of the Baffin Island troughs in which the LGM assemblages were mostly dominated by glacial debris-flows and turbidites were not included. Cores from Baffin Bay were selected to allow a north to south representativity and to avoid redundant information. In general, the lithofacies provided a good correlation between them on the basis of radiocarbon dating. For full description of the cores, readers are referred to the original publications—16PC⁵⁷; 34PC and 36PC⁵⁶; 61PC, 64PC, 73PC, 74PC and 77PC⁴⁵; 67PC²¹; SL174⁶⁰.

Radiocarbon ages were calibrated within the age-depth modelling process using the online software Calib 8.2 with the Marine20 radiocarbon age calibration curve⁸⁷ and a local reservoir correction (ΔR) of 87 ± 20 ⁸⁸ commonly used on northeastern Baffin Island^{26,45,57,60} (Supplementary Table 1). This reservoir correction is in line with the one currently used for radiocarbon date calibrations of central West Greenland^{34,71}, that indicate a reservoir correction (ΔR) of 140 ± 35 years⁸⁹. We recognize that an offset caused by a well-mixed ocean was most likely variable through time and the appropriate ΔR reservoir correction for the region might have been larger than the one used and provide younger ages.

However, this would not considerably change the interpretation of the ice shelf scenario.

Data availability

The swath bathymetric data collected in 2017 during expedition MSM66⁸⁵ have been deposited in the PANGAEA repository, available under <https://doi.org/10.1594/PANGAEA.902341>. The swath bathymetric data from ArcticNet cruises can be visualized on the Université Laval Géoindex + website (<http://geoindex-plus.bibl.ulaval.ca>). The Parasound profiles collected in 2017 during expedition MSM66⁸⁵ have been deposited in the PANGAEA repository, available under <https://doi.pangaea.de/10.1594/PANGAEA.944843>. The seismic reflection data along with the acquisition specifics are available on the Marine Data Holding public repository of National Resources Canada (<http://geogratis.gc.ca/>).

Acknowledgements

We are thankful to the captains, crews and scientific participants on the different cruises for their help and support during the expeditions. This project was funded by the ArcticNet Network of Centers of Excellence, Natural Sciences and Engineering Research Council of Canada (NSERC) and Sentinelle Nord (Apogée Canada) grants to P.L., the Deutsche Forschungsgemeinschaft (DFG) grants to B.D., C.G. and D.H. for ship-time and to D.H. for the International Research Training Group “ArcTrain” (IRTG 1904), as well as Université de Strasbourg grants to P.O.C. We also thank ArcTrain Canada for providing financial support to this project. This paper benefited from fruitful discussions with D. B. Praeg and C. Ó Cofaigh. The final version of this manuscript was greatly improved by thoughtful reviews from M. Margold, J. T. Andrews and two anonymous reviewers.

Author contributions

P.O.C. conceived the study and initiated this project in cooperation with P.L. and J.F.G. P.O.C. interpreted the geophysical data sets, wrote the paper and prepared the figures. P.O.C., P.L., J.F.G., B.D., C.G., D.H. and E.B. were involved in the discussion of the data and contributed to the final version of this paper.

Competing interests

The authors declare no competing interests.
