With atomic systems, optically programmed trapping potentials have led to remarkable progress in quantum optics and quantum information science. Programmable trapping potentials could have a similar impact on studies of semiconductor quasi-particles, particularly excitons. However, engineering such potentials inside a semiconductor heterostructure remains an outstanding challenge and optical techniques have not yet achieved a high degree of control. Here, we synthesize optically programmable trapping potentials for indirect excitons of bilayer heterostructures. Our approach relies on the injection and spatial patterning of charges trapped in a field-effect device. We thereby imprint in-situ and on-demand electrostatic traps into which we optically inject cold and dense ensembles of excitons. This technique creates new opportunities to improve state-of-the-art technologies for the study of collective quantum behavior of excitons and also for the functionalisation of emerging exciton-based opto-electronic circuits.

In semiconductors, spatially indirect excitons of bilayer heterostructures, e.g. of double quantum wells, provide a model example of dipolar quantum particles^{1–8}. To explore the exotic collective quantum phenomena predicted for indirect excitons^{9–11} studies have emphasized the creation of trapping potentials^{12–18} and gate defined electrostatic traps have led so far to the most advanced realizations^{6,19–23}. This technology relies on the dipolar interaction between the well oriented electric dipole of indirect excitons and a spatially varying electric field controlled by the gate electrodes. In electrostatic traps, indirect excitons are usually created by optically injecting electronic carriers, a process which can alter basic functionalities. For example, the optical injection of electrons and holes can result in carrier imbalance²³, even in a spatial separation of charges^{24,25}. We have also shown recently that photo-injected carriers can accumulate at the gate electrodes and then blur the excitons confinement²⁶. Here we show that the disruptive role of photo-injected carriers can be tailored in a way that yields an electro-optic control over the confinement of indirect excitons.

Results

Photo-excitation of the field-effect device. We studied indirect excitons confined in a GaAs double quantum well (DQW) embedded in a *n-i-n* field-effect device (see Figure 1.A and Methods). For this heterostructure we developed an all-optical control over the excitons confinement using sequences of pulsed laser excitations. Our approach relies first on a “preparation” beam tuned at 641.5 nm, i.e. at an energy slightly below the bandgap of the Al_{0.33}Ga_{0.67}As barriers surrounding the DQW²⁷. Thus, we used a “preparation” pulse to inject electronic carriers mainly in the *n*-doped contact electrodes, a small part of the “preparation” beam being also directly absorbed by the DQW²⁸. While most of the carriers created in the contacts generate a photo-current, a smaller fraction also produces an out-of-equilibrium population of charges accumulated at the *n-i* heterojunctions due to the potential barriers formed by the band offset between the *n*-GaAs and Al_{0.33}Ga_{0.77}As layers²⁹. At 350 mK, our bath temperature, the thermal activation may be too small ($k_B T \sim 30 \mu\text{eV}$) to overcome the potential barriers such that charges can remain accumulated at the *n-i* heterojunctions after a “preparation” pulse and then dress the internal electric field²⁶.

Mapping the internal electric field with indirect excitons. We first quantified the influence of the “preparation” beam on the amplitude of the internal electric field, E_{int} , by using a pump-probe sequence where a 300 ns long “preparation” pump pulse was followed 500 ns later by a weak excitation probe, from another laser beam at 790 nm. The probe excitation was tuned resonantly with the direct excitonic transition of the two quantum wells in order to inject electrons and holes directly in the DQW which then create a dilute gas of indirect excitons. The internal electric field is also weakly perturbed by the probe excitation, the photoluminescence emitted by the *n*-doped contacts being negligible compared to that obtained by excitation with the “preparation” beam. In these experiments, indirect excitons injected by the probe pulse served as a sensitive and non-perturbative probe for E_{int} : in the dilute regime, the indirect exciton emission energy, E_X , is governed by the dipolar interaction between

Figure 1 | (A) Sketch of the field-effect device energy levels. Electrons and holes are represented by full and open circles respectively, “preparation” and “writing” beams by the blue and red arrows respectively. The optical excitation is performed from the surface of the sample where the gate V_g is applied (right side). The grey areas underline the heterojunctions where photo-injected carriers can accumulate. (B) Variation of the energy (ΔE_X in black circles) and spectral width (Γ_X in red squares) of the indirect excitons photoluminescence as a function of the power of the “preparation” beam, P_{640} . $\Delta E_X = (E_X - E_X^{(0)})$ where $E_X^{(0)}$ is the emission energy without “preparation” pulse. The inset shows the variation of the mean photo-current in these measurements. (C) Spatially and spectrally resolved emission of indirect excitons loaded by a probe pulse (at 8.5 mW.cm^{-2}) turned on 500 ns after a “preparation” pulse of $10 \text{ }\mu\text{m}$ waist and power equal to 100 mW.cm^{-2} . The white line displays the profile of the “preparation” beam. All measurements were realized 20 ns after extinction of the probe pulse in a 20 ns wide time window and at 350 mK.

the excitonic dipole oriented perpendicularly to the DQW, $d \approx e \cdot 10 \text{ nm}$ (data not shown), and the internal field, such that E_X scales like $(-d \cdot E_{\text{int}})$.

For our field-effect device, we observed that the amplitude of the internal electric field is significantly enhanced by the “preparation” excitation (see Fig. 1.B). This is manifested by a red shift of E_X with increasing power of the “preparation” beam (P_{640}), in agreement with an accumulation of carriers at the contact electrodes (note that the injection of holes results in a deficit of electrons increasing the potential of the bottom electrode on the left hand-side of Fig. 1.A). However, we note that the red shift of E_X saturates at $\approx -4 \text{ meV}$ which indicates that the charge accumulation can become too large to be blocked efficiently by the potential barrier at the heterojunctions. Indeed, the saturation of E_X coincides with a steep increase of the mean photocurrent (see inset in Fig. 1.B).

Quite surprisingly, we also noted a strong lateral localization of excess charges over long timescales. This behavior was signaled by experiments where we used a narrow “preparation” beam ($10 \text{ }\mu\text{m}$ waist) while the probe beam was wide ($\sim 67 \text{ }\mu\text{m}$ waist). Then, 20 ns after the end of the probe pulse, the spatially and spectrally resolved emission of indirect excitons reveals that E_X is shifted to lower energies under the “preparation” beam excitation area, by $\Delta_t \sim 1.7 \text{ meV}$, while outside the emission occurs at a rather unperturbed energy. This manifests that the charge accumulation lasts for several hundreds of nanoseconds, and also that the carriers lateral diffusion is very slow, probably due to the n - i interface roughness which localizes excess charges, particularly at our sub-Kelvin bath temperature. Accordingly, the “preparation” pulse has imprinted an electrostatic

trap with a depth (Δ_t) almost two orders of magnitude greater than the thermal activation energy.

Programming the confinement of indirect excitons. To increase our degree of control over the excitons’ confinement, we included a “writing” pulse in our laser sequence. The “writing” beam was produced by another laser diode emitting at $\sim 790 \text{ nm}$ and had a two-fold purpose: Firstly, above a threshold excitation the “writing” beam leads to a heating of our sample to about ten degrees Kelvin³⁰, heating which can activate the transport of carriers accumulated at the contacts after an excitation by the “preparation” pulse. Secondly, the “writing” pulse allowed us to inject indirect excitons directly in the DQW while it is weakly absorbed by the contact electrodes, as for the probe excitation.

The heating of our sample by the “writing” beam is revealed by the dynamics of the photoluminescence emitted by indirect excitons at the end of a pulsed excitation (note that the “preparation” beam was not used here). Indeed, indirect excitons constitute a sensitive probe of the sample’s temperature as they experience a rapid thermalization in our two-dimensional geometry^{30–34}. Figure 2. A–D illustrates the exciton thermometry and shows that the photoluminescence emitted at the position of the “writing” beam suddenly increases, or jumps, at the end of a laser pulse. By contrast, $10 \text{ }\mu\text{m}$ outside the illuminated region this non-linearity is strongly reduced. These distinct dynamics underline the collapse of the so-called inner-ring, i.e. the thermalization within few nano-seconds of indirect excitons that were heated during the “writing” pulse and within the illuminated region^{30–34}. On the other hand, outside of the laser spot the

Figure 2 | (A–B) Spatially and spectrally resolved emission of indirect excitons at the falling edge (A) and 4 ns after (B) a “writing” pulse at 10 W.cm^{-2} and with a $6 \mu\text{m}$ waist. The beam is positioned at the center (position 0). (C) Emission profiles at the falling edge of the writing pulse and 4 ns later, solid and dotted lines respectively (the laser profile is shown by the red line). (D) Dynamics of the photoluminescence intensity at the position of the “writing” pulse (red) and outside (blue). The black line shows the best fit which yields a mono-exponential decay with a time constant equal to $138(3) \text{ ns}$. All measurements were realized with a 2 ns time resolution and at 350 mK .

photoluminescence jump is reduced which shows that this region was weakly heated during the laser excitation.

The effect of the “writing” beam onto the spatial distribution of carriers injected by a “preparation” pulse and trapped at the n -doped contacts is illustrated in Fig. 3. A–E. For these experiments we excited the field-effect device using a $8 \mu\text{m}$ wide “writing” beam positioned at the center of a large ($\approx 80 \mu\text{m}$ waist) “preparation” beam. Also, the delay between the “writing” and “preparation” pulses was set to 500 ns (Fig. 3.A). As shown in Figure 3.B, the emission of indirect excitons then exhibits a ring-shaped pattern 20 ns after the “writing” pulse. The inner dark region has a spatial profile reproducing closely the “writing” beam shape: there the photoluminescence has dropped by $\sim 50\%$ compared to a reference situation where no “preparation” beam is used (see Fig. 3.C–D). Incidentally, we note for this reference case that the emission has a spatial extension much larger than the “writing” beam (see Fig. 3.D): strong repulsive dipolar interactions between indirect excitons induce a large exciton diffusion^{32,35}.

The occurrence of the ring pattern in Fig. 3.B indicates that the central region is now a region where the internal field is low and from where the excitons are dragged away, indirect excitons being high-field seekers. To confirm this interpretation and measure the potential step for indirect excitons, a third probe beam was used and switched on 500 ns after extinction of the “writing” pulse (see Fig. 3.A). The spatial and spectral mapping of the indirect excitons photoluminescence was measured 20 ns after the probe pulse. As shown in Fig. 3.E we then observed that the emission occurs at a higher energy at the “writing” beam position than in the surrounding, by $\Delta_{\text{at}} \approx 2 \text{ meV}$. This measurement confirms directly that the amplitude of the internal field is reduced in the region illuminated by the “writing” beam. Hence, carriers injected by the “preparation” beam and trapped at the contacts have been depleted from this region by the “writing” pulse and we thus created a potential gradient expelling indirect excitons away from the beam position, i.e. a quasi-stationary anti-trap with a height Δ_{at} .

Hollow trap for indirect excitons. The previous technique can be easily extended to realize a hollow-trap for indirect excitons. Such

trap consists of a ring-shaped potential barrier³⁶. To engineer it, we solely shaped the “writing” beam into a ring (Fig. 4.A). Again we used a sequenced optical control where a spatially wide and uniform “preparation” pulse was followed by a ring-shaped “writing” pulse. We present in Fig. 4.B the spatially resolved emission 20 ns after the “writing pulse” when the field-effect device was not illuminated by the “preparation” beam. No trace of the “writing” beam shape is observed owing to the large diffusion of indirect excitons. On the contrary, when the sample is first illuminated by a “preparation” pulse (Fig. 4.C), the emission, 20 ns after the end of the “writing” pulse, is more intense (same color scale as in Fig. 4.B) and localized within the area defined by the “writing” beamshape. The writing pulse has defined a hollow-trap for excitons and built up a population of indirect excitons which relax rapidly toward the trap center. As shown in Fig. 4.D, this excitation scheme is efficient to create and confine a dense ensemble as the photoluminescence increases by as much as 30% at the center of the trap (see the blue area).

To further quantify the performance of the hollow-trap barrier, we injected indirect excitons directly at the center of the hollow-trap and monitored the exciton transport as we increased the density. Precisely, we used a complete laser sequence where “preparation” and “writing” pulses first imprinted a hollow trap, 500 ns before we applied a 300 ns long “loading” pulse produced by another laser diode emitting at 790 nm (see Fig. 5.A). The “loading” beam was positioned at the center of the trap and we used its intensity to vary the concentration of excitons confined in the trap. Also, note that the “loading” beam introduced an additional potential barrier converting the hollow into a ring trap.

As shown in Figure 5, for the confinement of indirect excitons we can distinguish two regimes as a function of the power of the loading beam (P_{790}). First, for $P_{790} \leq 1.5 \text{ W.cm}^{-2}$ we note that the exciton transport is well blocked by the hollow trap barrier, as revealed by a drop of the photoluminescence intensity outside the trap (red line in Fig. 5.D) where it is reduced by ≈ 2 –3 times compared to a reference situation where the ring shaped “writing” beam was not used (dashed blue line in Fig. 5.D). By contrast, excitons overflow the hollow-trap

Figure 3 | (A) Sketch of our laser sequence where 300 ns long “preparation”, “writing” and probe pulses are each separated by a 500 ns waiting time. The variation of the confining potential during the sequence is schematically displayed at the position the DQW (shown in orange) together with the charges accumulated at the top and bottom electrodes. (B–C) Photoluminescence emission of indirect excitons 20 ns after termination of the “writing” pulse (8 μm waist and at 1.5 W.cm^{-2}) with (B) and without (C) excitation by a “preparation” pulse (at 15 mW.cm^{-2}). (D) Intensity profiles taken at the center of the images (B) and (C), solid and dashed lines respectively, together with the profile of the “writing” beam (red line). (E) Spatially and spectrally resolved emission of indirect excitons 20 ns after extinction of the probe pulse. $\Delta_{at} \approx 2 \text{ meV}$ marks the amplitude of the anti-trapping potential and the white line displays the profile of the “writing” beam. All measurements were realized 20 ns after extinction of the “writing” (B–D) or probe (E) pulse in a 20 ns wide time window and at 350 mK.

barrier for $P_{790} \geq 1.5 \text{ W.cm}^{-2}$ (Fig. 5.C). In this regime, dipolar interactions between excitons enhance the mean-field energy which overcomes the barrier height^{30,35}. Accordingly, the concentration of excitons confined in the trap saturates, as underlined by the variation of the photoluminescence energy, E_X , as a function of power of the “loading” beam (Fig. 5.E). Indeed, while E_X is governed by the interaction between the excitons dipole and the internal electric field in the very dilute regime, it reveals the exciton concentration at higher densities where repulsive dipolar interactions between excitons are dominant and yield a blue shift of the photoluminescence emission proportional to the exciton density^{37,38}. As shown in Figure 5.E, in the hollow-trap we observed that E_X is enhanced by $\approx 2 \text{ meV}$ before saturating as we increased the power of the “loading” beam. Following recent theoretical works^{37,38}, we deduce that this blue shift corresponds to an exciton density of approximately $5 \cdot 10^{10} \text{ cm}^{-2}$, also we note that the maximum blue shift of the photoluminescence emitted in the hollow-trap well agrees with the barrier height (Δ_{at}) that we measured by mapping the landscape of the internal electric field (Fig. 3.E).

Discussion

In Figure 1.A we have shown that an excitation by the “preparation” beam red-shifts the photoluminescence emitted by indirect excitons, by up to $\approx 4 \text{ meV}$. On the other hand, resolving spatially the

emission of indirect excitons we have observed that a “preparation” pulse varies the energy of the photoluminescence emission by at most 2 meV. We attribute the discrepancy between these measurements as a manifestation of the injection of electronic carriers in the DQW by the “preparation” beam, notably as a result of the photocurrent generated by a “preparation” pulse. In that respect, previous studies^{24,25} have underlined that holes are captured more efficiently than electrons for an excitation at the energy of the “preparation” beam so that photo-injected holes can vary the charge of the DQW by (partially) annihilating residual electrons. For a DQW embedded in a field-effect device, such a background electron gas constitutes a typical drawback³⁹ which results from the modulation doping in the structure. Background electrons screen the potential confining indirect excitons³⁸, their annihilation by a “preparation” pulse would then effectively increase the excitons’ confinement, i.e. induces a red shift of the photoluminescence. Though we can not quantify this scenario, our experiments have revealed that a “preparation” pulse yields a smoother electrostatic landscape for indirect excitons injected 500 ns later by a probe beam. This is shown in Figure 1.B which underlines that the spectral width of the photoluminescence emitted after the probe pulse, Γ_X , drops at low intensities of the “preparation” beam, from $\Gamma_X \approx 2.8$ to 1.8 meV . Such a behavior is consistent with the annihilation of residual electrons by the “preparation” beam which then reduces the spectral diffusion.

Figure 4 | (B–C) Photoluminescence emission of indirect excitons for the ring-shaped “writing” beam shown in the panel (A) ($18\ \mu\text{m}$ radius and $3\ \mu\text{m}$ width at $0.75\ \text{W}\cdot\text{cm}^{-2}$) without (B) and with (C) excitation of the field effect device by a “preparation” pulse with $50\ \mu\text{m}$ waist (at $3.8\ \text{mW}\cdot\text{cm}^{-2}$). (D) Intensity profiles taken at the center of the images displayed in (B) and (C), dashed and solid lines respectively, together with the profile of the “writing” beam (red line). The filled area marks the increase of the photoluminescence when the hollow-trap is imprinted. All measurements were realized 20 ns after extinction of the “writing” pulse in a 20 ns wide time window and at 350 mK.

Figure 5 | (A) Sketch of the laser sequence where 300 ns long “preparation”, “writing” and “loading” pulses are separated by a 500 ns waiting time. The resulting exciton confining potentials are displayed schematically together with the charge accumulation at the contact electrodes. (B–C) Spatially and spectrally resolved photoluminescence of indirect excitons emitted 20 ns after extinction of a “loading” pulse at $1.5\ \text{W}\cdot\text{cm}^{-2}$ (B) and $5.6\ \text{W}\cdot\text{cm}^{-2}$ (C). The solid white line displays the profile of the ring-shaped “writing” beam and the dash white line the one of the “loading” beam. (D) Intensity profiles for the experiments shown in (B) when the hollow-trap barrier is imprinted (solid red line) or not (dash blue line). The green lines show the profile of the “writing” and “loading” laser beams. (E) Energy, E_{xs} , of the photoluminescence emitted by indirect excitons confined in the hollow trap as a function of the power of the “loading” beam. All measurements were realized 20 ns after extinction of the “loading” pulse in a 20 ns wide time window and at 350 mK.

Methods

Sample structure. We studied a field-effect device consisting of a *n-i-n* heterostructure embedding a double quantum well (DQW) made of two 8-nm wide GaAs quantum wells separated by a 4-nm $\text{Al}_{0.33}\text{Ga}_{0.67}\text{As}$ barrier. The DQW is placed between two $\text{Al}_{0.33}\text{Ga}_{0.67}\text{As}$ spacers of 200 nm thickness. In our experiments, a static potential ($V_g = -1.4$ V) was applied between two *n*-GaAs layers (Si doped with $n_{\text{Si}} \sim 5 \times 10^{17} \text{ cm}^{-3}$) which serve as gate electrodes. The top and back gates are 105 nm and 305 nm thick respectively. The back gate is electrically connected with a metallic contact deposited after etching of the sample. In our experiments, this electrode is grounded and electrically isolated from the sample holder by a 800 nm undoped GaAs layer incorporating a AlAs/GaAs superlattice. In addition, the top contact consists of a mesa with a $500 \times 500 \mu\text{m}^2$ aperture through which the photoluminescence is collected.

Experimental setup. The field-effect device was placed on the Helium 3 insert of a closed cycle Helium 4 cryostat (Heliox-ACV from Oxford Instruments). An aspheric lens with a 0.6 numerical aperture was embedded inside the cryostat in front of the sample and positioned by piezo-electric transducers (ML17 from MechOnics-Ag). We optimized the optical resolution of our microscope by introducing a mechanical coupling between the Helium 3 insert and the part holding the aspheric lens. Thus, the amplitude of mechanical vibrations does not exceed 2 microns (in a frequency range up to ~ 1 kHz) while the sample can be cooled to temperatures as low as 330 mK. In our experiments, the aspheric lens was used to excite the semiconductor sample but also to collect the photoluminescence that was reemitted. The latter was then directed to an imaging spectrograph coupled to an intensified CCD camera (Picostar-UF from La Vision) and we studied the emission of indirect excitons with a 2 ns time resolution at 500 kHz, either in real space or including a spectral resolution of 200 μeV .

To create the laser pulse sequences we used two CW diode lasers (DL-100 from Toptica) at 642 nm ("preparation" beam) and 790 nm ("writing" and probe beams). Both lasers were pulsed with electro-optic (integrated-optical modulator from JenOptic) and acousto-optic modulators (Crystal Technologies Inc.), controlled by a pulse sequencer. Thus, we engineered up to four independent excitation pulses with rising and falling edges of ~ 2 ns and ~ 5 ns for the electro-optic and acousto-optic switching respectively.
