Nonlinear dynamics underpin a vast array of physical phenomena ranging from interfacial motion to jamming transitions. In many cases, insight into the nonlinear behavior can be gleaned through exploration of higher order harmonics. Here, a method using band excitation scanning probe microscopy (SPM) to investigate higher order harmonics of the electromechanical response, with nanometer scale spatial resolution is presented. The technique is demonstrated by probing the first three harmonics of strain for a $\text{Pb}(\text{Zr}_{1-x}\text{Ti}_x)\text{O}_3$ (PZT) ferroelectric capacitor. It is shown that the second order harmonic response is correlated with the first harmonic response, whereas the third harmonic is not. Additionally, measurements of the second harmonic reveal significant deviations from Rayleigh-type models in the form of a much more complicated field dependence than is observed in the spatially averaged data. These results illustrate the versatility of n^{th} order harmonic SPM detection methods in exploring nonlinear phenomena in nanoscale materials.

Nonlinear systems are ubiquitous in nature, ranging from optics¹ to electronics to chemical reactions². An important subset of these phenomena concerns the study of nonlinear dynamics as manifested in solids, such as the motion of interfaces in ferroic materials^{3,4}, onset of superconductive⁵ and polar phases⁶, jamming transitions⁷, and electrochemical reactions⁸. These phenomena are an inherent part of technologically important materials and systems such as batteries, fuel cells, martensites, ferroics, and many more. As such, understanding sources and mechanisms of nonlinear responses and their role in emergent materials functionality is a key challenge of science.

One well known method of exploring nonlinear responses is to examine the higher order harmonics of the response of the material to an applied stimulus. For example, the use of second harmonic generation for probing crystal structures, surface states and magnetic structure⁹, whilst force-based scanning capacitance microscopy (which also utilizes the second harmonic) has been prevalent since the early 90's¹⁰. Despite this recognition of the role of higher order harmonic analyses, full understanding of the nonlinear dynamics over a variety of length scales has been stymied by a lack of suitable techniques. Presently, there is a lack of understanding of how effects driven by extremely local materials phenomena (in the nm– μm range) translate collectively into a much larger device-level impact.

Recently we have shown that the individual behavior of domain walls in ferroelectrics at the local level is different from that expected from the traditional Rayleigh framework¹¹. Here, a new SPM technique using n^{th} order harmonic detection and band-excitation is demonstrated that allows decoupling of responses in microscale volumes. A well-characterized ferroelectric material, namely epitaxial PZT, is used as a model system. It is found that the response of the second harmonic has locally non-monotonic behavior that forms spatial clusters which were thus far “invisible” when using methods limited to collecting spatially averaged data. It is speculated that these departures arise from local frozen disorder. These studies discover a rich spectrum of emergent spatially-inhomogeneous behaviors that may have broad implications for study of nonlinearity in other systems.

The basis for our approach rests on the fact that system responses can be approximated as linear for small stimuli. Either increasing the amplitude of the driving force or probing second and higher order harmonic responses permits exploration of nonlinear phenomena^{12,13}. Many phenomena, such as Joule heating¹⁴, electrostriction¹⁵, and electrostatic actuation¹⁰, rely on the second harmonic of the stimulus (e.g. electric field), whereas

primarily linear phenomena (such as intrinsic piezoelectric coupling) have much smaller higher order harmonic terms. As a result, the decomposition of the total response into harmonic components offers a path to decoupling individual response contributions to the total signal.

Seminal work on ferroelectrics capacitors was undertaken by Turik¹⁶ in the 1960s. Since then, research into the nonlinear properties of ferroelectric capacitor structures has been studied theoretically by Boser^{17,18}, (developing earlier statistical physics analyses by Kronmüller¹⁹) and extended with experimental investigations by Damjanovic^{20–22} and Trolier-McKinstry *et al.*^{23,24}. Other significant experimental^{25–27} and theoretical²⁸ studies on harmonic analysis have also been reported. However, these measurements have generally been performed on macroscopic systems, e.g. using top-electroded capacitor structures which sample large volumes of material. Hence, spatial resolution and therefore, the ability to correlate the response with microstructural features, have been unavailable. As a second challenge, higher order harmonics can be very small, with low susceptibility constants when compared to the linear couplings present. Finally, instrument-dominated contributions to the higher order harmonics are not uncommon.

As a model for nonlinear interaction mapping, we explore the first three harmonics of the strain response in a ferroelectric PZT capacitor. Similar capacitors have been well-studied macroscopically^{21,23,24}, and the theoretical framework for the harmonic responses has been developed recently^{29–31}. Furthermore, the technological applications of ferroelectric capacitors, to act as transducers³² and actuators³³, necessitate a more thorough understanding of the nonlinear dynamics in these systems.

In polycrystalline ferroelectrics, the strain and polarization responses at low to mid-range driving fields often follow the phenomenological Rayleigh Law, which can be expressed as:

$$d_{33} = d_{init} + \alpha_D E \quad (1)$$

$$x(E) = (d_{init} + \alpha_D E_0) E \pm \frac{\alpha_D}{2} (E^2 - E_0^2) \quad (2)$$

where d_{33} is the piezoelectric coefficient, x is the strain, $E = E_0 \sin(\omega t)$ is the applied field, E_0 is the maximum field in the sweep, α_D is the irreversible Rayleigh coefficient, and d_{init} is the reversible piezoelectric Rayleigh coefficient. The '+' refers to the reverse (decreasing) branch of the voltage sweep, and '-' refers to the forward (increasing) branch.

While the Rayleigh law has been shown to be largely valid for ferroic systems (under appropriate conditions, such as a Gaussian distribution of restoring forces acting on the domain wall¹⁸, low driving fields³⁴, a random distribution of pinning centers²⁰, and relatively small domain wall displacements¹⁸), the detailed mechanisms through which nanoscopic behavior (e.g. at a single domain wall) leads to Rayleigh behavior have remained mostly elusive. Physical descriptions of this phenomenological relationship have been offered since the works of Néel³⁵ and Kronmüller³⁶, and though theoretical models of enhancements in piezoelectric coefficients from domain wall motion are considerable in scope, the experimental evidence at small length scales remained rather limited^{37,38}. Detailed experimental investigations for ferroelectric capacitors were undertaken by Damjanovic and Trolier-McKinstry *et al.*, beginning in the 1990's. Their research indicated that many polycrystalline ferroelectrics obey the Rayleigh relationships (for both piezoelectric and dielectric coefficients). It was shown that the extrinsic contributions to the dielectric and piezoelectric coefficients are consistent with irreversible domain wall motion in the sample, as confirmed by recent high-resolution *in situ* x-ray diffraction studies^{39,40}.

The Rayleigh relations provide the simplest mathematical framework to study the nonlinear dynamics in this system. To investigate the expected response from higher order harmonics, Fourier

Table 1 | Expected harmonic terms from the 'Dynamic Poling' model resulting from nearly reversible displacement of domain walls

	Linear in E	Quadratic in E
1 st order harmonic	$d_0 E_0 \sin(\omega t)$	$\alpha_D E_0^2 \sin(\omega t) + \frac{4\alpha_D E_0^2}{3\pi} \cos(\omega t)$
2 nd order harmonic	$\frac{\beta d_0 E_0}{2} \cos(2\omega t)$	$\frac{\beta' d_0 E_0^2}{2} \cos(2\omega t)$
3 rd order harmonic	0	$\frac{4\alpha_D E_0^2}{15\pi} \cos(3\omega t)$

expansion of the Rayleigh equation (2) can be carried out; this leads to only odd-order harmonic components that contribute to the strain⁴¹. Furthermore, the third and higher order harmonic terms are characterized by a quadratic dependence of the strain on the driving field²². In many ferroelectrics, extrinsic contributions to the piezoelectric coefficients arise primarily from the motion of ferroelastic domain walls^{42,11}. However, certain samples in which ferroelastic walls were not active still exhibited a linear dependence of the piezoelectric coefficient on the driving field⁴³. To explain the discrepancy, the Rayleigh model was modified by Bassiri-Gharb *et al.*³⁰ to include the effect of a domain wall (or any other interface) moving nearly-reversibly under applied fields in a 'dynamic poling' model. In such a situation, the d_{init} , which was originally constant, becomes time and field-dependent, i.e. $d_{init} = d_0 [1 + (\beta + \beta' E_0) \sin(\omega t)]$, reflective of a domain wall moving in-phase with the applied (sinusoidal) bias, and with the displacement linearly proportional to the applied field. Substituting this into equation 2, and developing the Fourier expansion³⁰ produces the higher order harmonics and their field dependencies, which are organized in the table above for the first three harmonics (Note: static terms have been neglected, as they are not measured). It should also be noted that an additional contribution to the second harmonic arises from electrostriction.

Note that a similar analysis to that given above can be performed for more complex cases that include electrostrictive and spontaneous contributions to the total strain³¹ (see Supplementary S1).

From Table 1, it is clear that measurement of harmonic terms independently will allow decoupling of contributions to the strain from reversible and irreversible domain wall motions, providing the intrinsic electrostrictive strain is separately accounted for. A determination of the 3rd order harmonic term (expected to scale as E^2), will allow the contributions from the irreversible motions of the domain walls to be determined, while the electrostrictive-like contributions to the strain from the reversible domain wall motions (which will add

Figure 1 | General operating principle for nth harmonic detection. Using the band excitation method, a band of frequencies centered around ω_0/n is excited, and the n^{th} harmonic response is (simultaneously) measured at the contact resonance ω_0 .

Figure 2 | Piezoresponse amplitude for 1st, 2nd and 3rd harmonics, and mean response. The mean response for the three harmonics is shown in (a). The second and third harmonics are plotted on the right axis, and are two orders of magnitude weaker than the first. (b–d) The 50×50 grid ($5 \mu\text{m} \times 5 \mu\text{m}$) spatial maps of the piezoresponse amplitude (a.u.) at $V_{ac} = 2$ V are shown for (b) first, (c) second and (d) third harmonics. The white pixels in these spatial maps are points where a proper SHO fit was not possible.

to the real electrostrictive term) can be determined by calculating the 2nd order harmonics. Furthermore, β and β' can be separated if the field-dependencies of the response are measured. However, it is not yet clear whether such macroscopic models remain valid in the mesoscopic scale, and the length limits¹¹ of these models have not been tested. In the next section, a technique to resolve these higher order harmonics, analyze the field dependencies, and correlate them locally at the nanoscale is discussed.

Results

The band-excitation (BE-) scanning probe microscopy technique for determining the first-order harmonic electromechanical response (piezoresponse) has been reported elsewhere⁴⁴. Briefly, a band of frequencies is excited around the contact resonance of the cantilever (Figure 1, red square), and the response across the band is

simultaneously measured and Fourier transformed to yield the system's total response. The BE-response is then fit to a simple harmonic oscillator (SHO) function to extract the response amplitude, phase, resonance and quality factor of the cantilever. The BE-response is measured as a function of AC voltage. By judicious selection of the excitation function, it becomes possible to decouple the sample nonlinearity from the nonlinearity of the tip-surface junction⁴⁵. This procedure is repeated across a grid of points on the sample, and the data can be fit to a predefined function at each point, to yield coefficient maps of the various fitting parameters. An extension to this technique (Figure 1) is the measurement of the n^{th} harmonic ($n = 1, 2, 3, \dots$), where instead of exciting the band of frequencies at the contact resonance ω_0 , the excitation is around $\omega_0 n$. The measurement is still performed at the contact resonance; note that this technique has been demonstrated in a limited fashion

Figure 3 | Investigation of first harmonic response. (a) Fit-type map displaying regions which show linear, ($P = \alpha_1 V_{ac} + c_1$), (blue) and quadratic, ($P = \alpha_1 V_{ac}^2 + \alpha_2 V_{ac} + c_1$), (green) behaviors. for $n = 2$ previously, though only for constant AC amplitude⁴⁶. Measurement of higher order harmonics in this manner has two key advantages. First, there is a significant enhancement of the signal due to electromechanical coupling to the contact resonance of the cantilever; secondly, for higher order harmonics, if the excitation was at the contact resonance, then the detection would likely be in the MHz range, which is beyond the range of many SPM-based lock-in amplifiers.

The domain structure of the tetragonal PZT capacitor was initially explored through Piezoresponse Force Microscopy (PFM), see Supplementary S2. The sample is a ~ 611 nm thick (001) tetragonal $\text{Pb}(\text{Zr}_{0.45}\text{Ti}_{0.55})\text{O}_3$ epitaxial film grown on (001) SrTiO_3 substrate by pulsed laser deposition. X-ray diffraction indicated the sample is phase-pure. The film has a coercive field $E_c = \sim 44$ kV/cm.

The response of the first three harmonics was then investigated as a function of probing voltage (V_{ac}), which in increments of 0.0625 V ranged from $V_{ac} = 0.0625$ V to $V_{ac} = 2$ V (corresponding to measurement up to $0.75E_c$), on a 50×50 grid in a $5 \mu\text{m} \times 5 \mu\text{m}$ area yielding a spatial resolution of 100 nm per grid point. Maps of the piezoresponse and resonance as a function of V_{ac} for all three harmonics are provided in Supplementary S3 and are also included as videos. The average response as a function of the applied voltage, for all three harmonics is plotted in Fig. 2(a). Error bars are plotted in black. The first harmonic signal appears largely linear, whereas the second and third harmonics can be better described by higher order polynomial functions. It is clear that the second and third harmonics of the piezoresponse are two orders of magnitude smaller than the first harmonic (Supplementary S4).

The voltage slices for the first piezoresponse of the three harmonics, i.e. the spatial maps, are shown for $V_{ac} = 2$ V in Fig. 2(b–d). The spatial maps for the resonance are given in Supplementary S5. The white pixels in these spatial maps are points where the response is close to zero, and thus were not amenable to fitting. The third harmonic in particular shows only a small number of spatial points that exhibit a measurable response. Interestingly, these tend to group in clusters. The second harmonic spatial map appears to show some correlation with the regions of high response in the first harmonic spatial map. The dynamic poling model, coupled with the observation that the second harmonic is spatially inhomogeneous, suggests that a portion of the second harmonic could be due to nearly reversible domain wall motion. That is, if the high local linear piezoelectric coefficient is enhanced by the existence of a contribution from nearly reversible domain wall motion, then it is reasonable that the second harmonic signal is high in the same regions of the sample.

Spatial correlations with the third harmonic and the other two harmonic response maps, however, are not evident.

In order to study the local responses, i.e. piezoresponse amplitude at a particular (X,Y) coordinate, in more detail, the dependence of the first harmonic piezoresponse amplitude on the probing voltage (V_{ac}) was investigated. The local response was found to be a linear function of V_{ac} ($P = \alpha_1 V_{ac} + c_1$) in some regions, and a quadratic function of V_{ac} ($P = \alpha_1 V_{ac}^2 + \alpha_2 V_{ac} + c_1$) in others. A ‘fit-type’ map based on these two model response types considered shows these regions in Fig. 3(a). The majority of the studied area is linear (blue), but small clusters exhibiting quadratic behavior (green) also exist. However, the nonlinearity is relatively small for this film, suggesting that any domain walls that are contributing to the signal are doing so primarily in a reversible manner. The average response from the linear and quadratic regions is plotted in Fig. 3(b). The relatively small nonlinearity observed in this film may be the cause of the weak 3rd harmonic signal, which should be locally correlated with the irreversible Rayleigh coefficient (Table 1). The effective piezoelectric coefficient d_{eff} shown in Fig. 3(c), was calculated from the expression,

$$d_{eff} = \frac{\Delta P}{\Delta V_{ac}} = \frac{P(V_{ac}) - P(V_r)}{V_{ac} - V_r}, \quad (3)$$

where ΔP and ΔV_{ac} are, respectively, the change in the overall average piezoresponse and AC probing voltage from the reference condition ($P(V_r), V_r$) where $V_r = 0.0625$ V. The plot of d_{eff} vs. probing field reveals that for $V_{ac} < 0.6$ V (corresponding to $V_{ac} < 0.22E_c$), the d_{eff} is changing linearly with respect to applied field, suggesting that the measurements are within the Rayleigh regime.

Discussion

A first attempt was made to use the dynamic poling model to describe the quadratic function of the piezoelectric responses. It was found that since the majority of the data for higher harmonics were taken at voltages that exceed the Rayleigh regime, the results were not acceptable, i.e. the quality of the power-law fitting was such that the analytical model cannot be considered to be descriptive. Additional features in the local response at a particular (X,Y) coordinate shown in Fig. 4(a) appear very different from the average second harmonic response shown in Fig. 2(a). This type of response is clearly not amenable to quadratic fits (unlike the average second harmonic response), and it is comprised of a jagged response which we refer to as ‘fine structure’ overlaid on a monotonic increase. It is noted here that these fine structure features are found at nearly every point in the (X,Y) spatial map for the second harmonic, not just at this particular

Figure 4 | Fine-structure analysis in 2nd harmonic. An example of how the ‘Fine Structure’ (FS) in the 2nd harmonic piezoresponse at a single (X,Y) point was obtained is shown in (a). The error bars shown correspond to 99% confidence intervals of the data points. The difference between the raw piezoresponse (P) and the background (B) constructed gives the FS data (black line, $F=P-B$). Subsequent analysis as explained in the text allows construction of an FS mask (b), which shows the most dominant eigenvector w_1 (i.e. fine structure feature) at each (X,Y) coordinate in the studied region. Color code employed: blue, green, red, yellow and purple, respectively, for w_1 (i.e. 1FS) to w_5 (i.e. 5FS). (c) Average 2nd harmonic response for the different colored regions in (b) with the overall average piezoresponse of the whole region inspected. The number of points stands for the total number of points populating the corresponding region in FS mask shown in (b).

point. Therefore, to study these fine structure features in more detail, a background was constructed using the bottom half segment of the convex hull of the data points to represent the monotonically increasing trend as shown by the red line in Fig. 4(a). (Supplementary S6). This background (B) was calculated for the second harmonic response at each (X,Y) position, and was subtracted from the raw second harmonic piezoresponse (P) to produce a *Fine Structure* matrix F , i.e. $F = F(X, Y, V_{ac})$. Here, the aim is to capture the portion of the data that represents deviation from a monotonically increasing trend, i.e. the convex hull of the data points. Principal Component Analysis (PCA)⁴⁷, a convenient technique for visualizing trends in multidimensional datasets, was then performed on F , yielding a set of N eigenvectors $w_i(V_{ac})$ with associated eigenvalues $\alpha_i(X, Y)$ which allows the dataset F to be expressed as $F(X, Y, V_{ac}) = \sum_i^N \alpha_i(X, Y) w_i(V_{ac})$. PCA is a decomposition, carried out in such a way that the first eigenvector (principal component) w_1 accounts for the highest statistical variation in the dataset, the second component w_2 accounts for the highest variation with the constraint it be orthogonal to the first eigenvector, and so on until the entire dataset can be described from the new set of eigenvectors. The corresponding loadings (eigenvalues) can be plotted spatially. For the PCA on F (Supplementary S7), the first eigenvector w_1 contains one peak and corresponds to exactly one fine structure feature (1FS) appearing in the second harmonic response, the second eigenvector w_2 contains one peak and one valley and corresponds to two features (2FS), and so on for the first five eigenvectors (higher order eigenvectors are dominated by noise). The number of fine structure features is equal to the total number of peaks and valleys present in the eigenvector. The data $F(X, Y, V_{ac})$ obtained at each point (X,Y) can be associated with the eigenvector w_i for which the eigenvalue α_i is the largest one at that point (i.e., the largest projection). In this manner, fine structure features (1FS to 5FS) can be determined for each point (X,Y) and plotted spatially to obtain an FS mask (or regional deconstruction) as shown in Fig. 4(b).

Interestingly, this regional deconstruction shows that the fine structure features tend to cluster, and is particularly evident for points which display one (blue), two (green) and three (red) fine structure features. The associated plots of the average second harmonic response from each of these colored regions are given in Fig. 4(c) along with their overall average response. More information

on the local cluster behavior can be found in Supplementary S8. Surprisingly, averaging of all the local responses leads to an overall average response [solid black line in Fig. 4(c)] that can be better approximated by a polynomial function, in stark contrast to the local response. However, the sum average of the second harmonic appears to be much more closely aligned with the expected macroscopic response, indicating that the fine structures are in fact arising from local, frozen disorder in the material.

In summary, a generalized scanning probe microscopy technique to explore nonlinear dynamics, through n^{th} -order harmonic detection with nanometer spatial resolution is presented. For the first time, the appearance of fine structure features in the second harmonic are identified and suggested to arise from local frozen disorder. The novel technique used here potentially allows the length scales of macroscopic theories to be tested, and furthermore sheds light on how properties develop at the nanoscale. This study reveals the potential of harmonic detection in uncovering nonlinear dynamics in material systems.

Methods

The n^{th} harmonic detection system was implemented on a commercially available AFM platform (Cypher Model, Asylum Research) equipped with in-house band-excitation performed with National Instruments PXI-based electronics with Labview and Matlab-based scripts. The sample is a ~ 611 nm thick (001) tetragonal $\text{Pb}(\text{Zr}_{0.45}\text{Ti}_{0.55})\text{O}_3$ epitaxial film grown on (001) SrTiO_3 substrate by pulsed laser deposition. X-ray diffraction indicated the sample is phase-pure. The film has a coercive field $E_c \sim 44$ kV/cm. Numerical analysis was performed with Matlab v7.

Acknowledgements

STM and DM gratefully acknowledge support from the National Science Foundation (DMR 1005771) and a National Security Science and Engineering Faculty Fellowship. R.K.V., M.B.O. and N.V. acknowledge support from the ARC Discovery Project scheme. R.K.V. and V.N. acknowledge an Overseas Travel Fellowship by the Australian Nanotechnology Network and the user facilities at ORNL-CNMS under user proposal No. 2011–281. The research at ORNL (Y.K., S.J., S.V.K.) was conducted at the Center for Nanophase Materials Sciences, which is sponsored at Oak Ridge National Laboratory by the Division of Scientific User Facilities, U.S. Department of Energy.

Author contributions

R.K.V. performed the experiments, analyzed data, prepared figures and wrote the paper. M.B.O. analyzed the data, wrote the Matlab scripts for data analysis and fitting, prepared figures and co-wrote the paper. R.K.V. and M.B.O. contributed equally to this manuscript. I.R., Y.K. and S.J. helped perform the experiments, developed and implemented the n^{th} harmonic excitation technique on the Asylum platform. D.M. prepared the sample used for study, analyzed data and performed relevant characterization experiments, and co-wrote the paper. S.T.M., V.N. and S.V.K. planned the study, analyzed the data and co-wrote the paper. All authors reviewed the manuscript.
