One way of increasing the energy density of lithium-ion batteries is to use electrode materials that exhibit high capacities owing to multielectron processes. Here, we report two novel materials, Li_2TiS_3 and Li_3NbS_4 , which were mechanochemically synthesised at room temperature. When used as positive-electrode materials, Li_2TiS_3 and Li_3NbS_4 charged and discharged with high capacities of 425 mA h g^{-1} and 386 mA h g^{-1} , respectively. These capacities correspond to those resulting from 2.5- and 3.5-electron processes. The average discharge voltage was approximately 2.2 V. It should be possible to prepare a number of high-capacity materials on the basis of the concept used to prepare Li_2TiS_3 and Li_3NbS_4 .

Lithium-ion batteries with high energy densities are highly desirable as power sources for electric vehicles and electric power storage devices¹. The development of new high-capacity active materials for electrodes is essential for fabricating such batteries.

Positive electrodes, such as those made of layered and spinel-type lithium metal oxides and lithium metal phosphates, have been used in lithium-ion batteries. These electrodes usually have one equivalent of lithium per transition metal or less, and their capacities are less than 200 mA h g^{-1} . Of late, layered lithium metal oxides with more than one equivalent of lithium per transition metal are being actively researched and developed as novel positive-electrode materials with capacities greater than 200 mA h g^{-1} . However, it is still difficult to achieve reversible capacities greater than 300 mA h g^{-1} in layered lithium metal oxides. Transition metals act as the redox centre in many conventional active materials. In most cases, a single-electron reaction occurs during charging and discharging, and multielectron reactions, which are necessary for higher capacities, do not take place. This is partly because of (i) the instability of the active materials after the multielectron reactions, particularly in the charged state, where the higher valence state of transition metals is contained, and (ii) the irreversibility of the structures against larger changes in the valence state of the constituent metal ions. However, several exceptions have been reported. For instance, it had been reported that lithium vanadium oxides, $\omega\text{-Li}_x\text{V}_2\text{O}_5$, show a capacity of more than 300 mA h g^{-1} and that approximately 3 lithiums per formula unit can be insert and removed from them; this corresponds to 1.5 electron processes per vanadium atom². Although most positive-electrode materials charge and discharge mainly through the redox reaction of the transition metal, the redox reaction of anions as well as that of the transition metals should be exploited to achieve higher capacities. That is to say, it is essential that charge and discharge reactions involving more than two electrons should occur in the electrode materials. Therefore, the challenge is to develop new active materials that can charge and discharge through processes that involve more than two electrons.

Conversion electrodes, which involve the formation and decomposition of Li_2O , Li_2S , or LiF and the reduction and oxidation of metal nanoparticles, exhibit high capacities because their constituent materials undergo multi-electron reactions^{3–5}. Most conversion electrodes show low potential and thus are usually employed as negative electrodes. A few conversion electrode materials, such as metal fluorides, show high capacities and voltages⁵. However, their reversibility is usually low because of the large structural changes that occur during charging and discharging.

Metal sulphides have also been studied as potential positive-electrode materials^{6–9}. An advantage of metal sulphides is that their capacity is related to the sulphur redox reaction in addition to the redox reaction of the transition metal; this leads to a high capacity owing to the multielectron redox reaction. For example, crystalline TiS_3 charges and discharges with reversible capacities greater than 300 mA h g^{-1} , a value that corresponds to processes involving more than two electrons^{6–9}. However, it has been reported that the reversibility of TiS_3 is low,

probably owing to the transformation of its polyhedral structure from a trigonal prism to a more stable octahedron^{6–8}. It was recently reported that the amorphisation of TiS_3 via mechanical milling improves its performance as an electrode material^{10–12}. Amorphous TiS_3 exhibits a three-dimensional framework, which would be favourable for stabilising its structure against the large volume changes caused by the charge-discharge process. The development of electrode materials with structures that remain stable during multi-electron processes is thus strongly desired.

We focused on the lithium predoping of metal sulphide electrodes because (i) it might stabilise the structure and (ii) a lithium-containing positive-electrode material is highly desirable; commercial negative electrodes usually do not contain lithium. In contrast to lithium metal oxides and metal sulphides, lithium-containing metal sulphides have not been widely studied; a few exceptions are Li_2FeS_2 and $\text{LiTi}_y\text{M}_{1-y}\text{S}_2$ ($\text{M} = \text{V}, \text{Cr}, \text{or Fe}$), etc.^{13–15}. The development of new lithium-containing metal sulphides (Li_xMS_y) has been a challenge. However, it should be possible to fabricate new crystalline-phase materials with high capacities and good structural reversibility by extracting/inserting Li in lithium-containing metal sulphides.

Here, we report the development of two novel lithium transition metal sulphides, Li_2TiS_3 and Li_3NbS_4 , which were fabricated *via* mechanochemical synthesis. The structures and electrode performances of the sulphides were investigated. We found that Li_2TiS_3 and Li_3NbS_4 exhibited reversible charging and discharging with high capacities of 425 and 386 mA h g^{-1} , respectively; these values correspond to processes involving 2.5 and 3.5 electrons, respectively.

Results

Figure 1a shows the X-Ray diffraction (XRD) patterns of TiS_2 , Li_2S , a mixture of TiS_2 and Li_2S that was not mechanically milled (0 h), and Li_2TiS_3 samples prepared by mechanical milling (MM) for 20, 40, 60, 80, and 100 h. Diffraction peaks corresponding to TiS_2 and Li_2S were not evident after the milling process; however, several new peaks appeared. The XRD patterns of Li_2TiS_3 after MM for 40, 60, and 100 h were similar. The broad peak observed at $2\theta = 10\text{--}25^\circ$ was owing to the Kapton® film.

Figure 1b shows the XRD pattern of Li_2TiS_3 prepared by MM for 40 h and the simulated pattern of Li_2TiS_3 with a rock-salt-like structure ($Fm\bar{3}m$). It was assumed that its unit cell contains four formula units of $[\text{Li}_{2/3}/\text{Ti}_{1/3}]_{4a}\text{S}_{4b}$, and the cell parameter is $a = 5.06 \text{ \AA}$. Table 1 shows the simulated powder X-ray data obtained using the software program Powder Cell¹⁶. The peak positions of the prepared Li_2TiS_3 sample were consistent with those of the simulated rock-salt-type Li_2TiS_3 . This suggests that the synthesised Li_2TiS_3 sample had a rock-salt-type structure. Furthermore, the intensity ratios of the XRD peaks of the prepared Li_2TiS_3 sample were in good agreement with the simulated ones for Li_2TiS_3 , indicating that the Ti occupancy in the 4a sites was approximately 0.33. Pattern fitting, performed using the program RIETAN-2000¹⁷, also indicated that the Li and Ti occupancies in the 4a sites were approximately 0.665(4) and 0.335(4), respectively. To the best of our knowledge, this is the first report of a lithium titanium sulphide with a rock-salt-like structure.

The rock-salt-type Li_2TiS_3 was employed as an electrode active material for lithium secondary batteries. Figure 2a shows the charge-discharge curves for the first 5 cycles of the cells fabricated using Li_2TiS_3 . The initial charge and discharge capacities were 273 and 425 mA h g^{-1} , respectively. Figure 2b shows the charge-discharge characteristics as a function of the lithium content. It was found that approximately 1.6 lithium atoms per formula unit could be extracted during the initial charging process and 2.5 lithium atoms could be inserted into the structure during the initial discharging process. The extraction and insertion of 2.5 lithium atoms into the structure of Li_2TiS_3 was reversible during repeated cycling. Thus, this electrode active material could contain more than 2 lithium atoms in its structure; the structure could be charged and discharged such that it

Figure 1 | XRD patterns of Li_2TiS_3 . (a) XRD patterns of TiS_2 , Li_2S , a mixture of TiS_2 and Li_2S that was not mechanically milled (0 h), and Li_2TiS_3 samples prepared by mechanical milling (MM) for 20, 40, 60, and 100 h. ranged from $\text{Li}_{0.4}\text{TiS}_3$ to $\text{Li}_{2.9}\text{TiS}_3$ over voltages of 1.5–3.0 V. The initial charging and discharging curve exhibited significant overlap with the second and third curves for the structure ranging from $\text{Li}_{0.4}\text{TiS}_3$ to Li_2TiS_3 , suggesting that the charge-discharge mechanism remained unchanged. Figure 2c shows the cycle performance of the cell fabricated using Li_2TiS_3 . The discharge profiles did not change drastically over 5 cycles; however, the capacity of the cell faded after the 10th cycle.

2	2	0	51.01	1.79	61
3	1	1	60.65	1.53	5
2	2	2	63.65	1.46	19
4	0	0	75.03	1.27	8
3	3	1	83.15	1.16	2
4	2	0	85.81	1.13	23
4	2	2	96.45	1.03	18

Figure 2 | Electrode performance of Li_2TiS_3 . (a) Charge-discharge curves of the cell fabricated using Li_2TiS_3 . Cut-off voltages were 1.5–3.0 V (versus a Li counter electrode). (b) Charge-discharge curves, with the number of lithium atoms per formula unit as the X-axis. (c) Cycling performance of the cell fabricated using Li_2TiS_3 .

To further investigate the electrochemical reactions occurring during the charge-discharge processes, *ex situ* XRD measurements were performed for Li_xTiS_3 with $x = 2.0, 1.0, 0.4, 1.4$, and 2.6 (Figure 3). The peaks became broad after a 1.0-electron charge, as shown in Figure 3b. Further, the peaks became even broader and decreased in intensity after the charge to $\text{Li}_{0.4}\text{TiS}_3$ (Figure 3c). Some of these broader, lower-intensity peaks in Figure 3c were identified as being attributable to ZrO_2 , which could have contaminated the test samples during the ball-milling process. Finally, after the discharge to $\text{Li}_{1.4}\text{TiS}_3$ (Figure 3d) and $\text{Li}_{2.6}\text{TiS}_3$ (Figure 3e), the peaks became sharper and increased in intensity. These results indicate that the extraction of lithium atoms from Li_2TiS_3 results in amorphisation and that reverse reactions occur during the discharge process. It should be noted that the XRD pattern corresponding to the rock-salt-type sample was observed after discharging to $\text{Li}_{2.6}\text{TiS}_3$. This suggests that the volume change during charge and discharge can be expected to occur in a three-dimensional manner.

To evaluate the cyclability of Li_2TiS_3 , an all-solid-state cell was constructed using Li_2TiS_3 as the electrode material. It is known that a number of electrode materials show high cyclability when used in

Figure 3 | XRD patterns of Li_xTiS_3 before and after the charge-discharge measurements. The patterns correspond to $x =$ (a) 2.0, (b) 1.0, (c) 0.4, (d) 1.4, and (e) 2.6.

all-solid-state cells. Figure 4a shows the charge-discharge curves of the all-solid-state cell at 50°C . Figure 4b shows the cycling performance of the all-solid-state cell. The cell exhibited high capacity retention, retaining 97% of its capacity from the 5th to the 50th cycle.

Figure 4 | Electrode performance of Li_2TiS_3 in an all-solid-state cell. (a) Charge-discharge curves of the all-solid-state cell fabricated using Li_2TiS_3 at 50°C . Cut-off voltages were 0.9–2.4 V (versus a Li-In counter electrode). The cell was precycled at 30°C . Current densities were 0.1 mA cm^{-2} for the 1st–4th cycles and 0.5 mA cm^{-2} after the 5th cycle. (b) Cycling performance of the all-solid-state cell fabricated using Li_2TiS_3 at 50°C .

Figure 5 | Characterisation of Li_3NbS_4 . (a) XRD pattern of Li_3NbS_4 prepared by MM for 40 h and the simulated XRD pattern of Li_3NbS_4 with a rock-salt-type structure ($Fm\bar{3}m$) obtained using the cell parameter $a = 5.13$. (b) Charge-discharge curves of the cell fabricated using Li_3NbS_4 and a liquid-based electrolyte. Cut-off voltages were 1.5–3.0 V (versus a Li counter electrode). (c) Cycling performance of the cell fabricated using Li_3NbS_4 .

Thus, Li_2TiS_3 exhibits high reversibility when subjected to charge-discharge cycling.

A number of novel lithium metal sulphides can be developed through mechanochemical synthesis on the basis of the concept employed for altering the structure of Li_2TiS_3 . Here, we show an example of one such material, Li_3NbS_4 , which has a structure similar to that of Li_2TiS_3 and was prepared by mechanochemical synthesis from Li_2S , NbS_2 , and S_8 . Figure 5a shows the XRD pattern of Li_3NbS_4 . The XRD pattern is similar to that of Li_2TiS_3 . Therefore, Li_3NbS_4 should also have a cubic structure, with the cell parameter $a = 5.13$ Å. Figure 5b shows the charge-discharge curves of the cell fabricated using Li_3NbS_4 ; 1 M LiPF_6 in a mixture of ethylene carbonate (EC) and dimethyl carbonate (DMC) was used as the electrolyte. The initial charge-discharge behaviour was similar to that of Li_2TiS_3 . The reversible capacity was 386 mA h g^{-1} , which corresponds to 3.5-electron processes. Figure 5c shows the cycling performance of the Li_3NbS_4 cell. The cell exhibited better cycling performance than that of the Li_2TiS_3 cell; this was despite the fact that the charging and discharging occurred owing to 3.5-electron processes in the case of the former. The electronic conductivities of compressed pellets of

powdered Li_2TiS_3 and Li_3NbS_4 were 8×10^{-6} and $2 \times 10^{-3} \text{ S cm}^{-1}$, respectively. These values are likely related to the electronic conductivities of the compounds.

The elucidation of the charge-discharge mechanism should result in the development of new electrode materials that exhibit better performances. To be able to determine where the excess lithium atoms exist in the sulphides is the most important goal as it will lead to the synthesis of the novel high-capacity electrode materials. Further studies on this topic are currently underway.

The calculated gravimetric energy densities of $\text{Li}/\text{Li}_x\text{TiS}_3$ ($0.4 \leq x \leq 2.9$) and $\text{Li}/\text{Li}_x\text{NbS}_4$ ($0.4 \leq x \leq 3.9$) were 850 and 780 Wh kg^{-1} . These values are larger than that for a typical positive electrode of LiCoO_2 , for which the energy density of $\text{Li}/\text{Li}_x\text{CoO}_2$ ($0.4 \leq x \leq 1$) is 660 Wh kg^{-1} . The combination of positive and negative electrodes is an important aspect. In order to use Li_2TiS_3 and Li_3NbS_4 as positive electrodes, their initial lithium content should be increased, that is, discharged state materials should be prepared, or lithium-containing negative electrodes such as lithium and lithium-alloy should be used. To conclude, in this study, we prepared the novel materials Li_2TiS_3 and Li_3NbS_4 from Li_2S , TiS_2 , NbS_2 and S_8 via mechanochemical synthesis using ball milling. Li_2TiS_3 was used as an electrode active material for a lithium secondary battery; it charged and discharged with initial charge and discharge capacities of 273 and 425 mA h g^{-1} , respectively. The average discharge voltage was approximately 2.2 V. Similarly, Li_3NbS_4 was also used as an electrode active material and showed a high capacity of 386 mA h g^{-1} . Reversible charging and discharging were confirmed, despite the processes being multielectron ones.

We have synthesised only two novel lithium metal sulphides through a mechanochemical method. However, it should be possible to fabricate a number of novel lithium metal sulphides using this method.

Methods

A mechanochemical synthesis method was employed to fabricate the lithium titanium sulphides. Mechanochemical synthesis involves the promotion of chemical reactions using mechanical energy. There are many merits of this method, such as the ability to prepare nanoparticles directly using a simple homogeneous reaction at room temperature. The primary advantage of mechanochemical synthesis is the ability to obtain the final product in a metastable state, which is difficult through conventional methods. In particular, amorphous materials and materials with highly symmetrical three-dimensional crystal structures can be obtained.

Li_2TiS_3 was mechanochemically synthesised at room temperature using a planetary ball mill apparatus (P-7, Fritsch GmbH). Lithium sulphide (Li_2S , 99.9%, Mitsuwa Pure Chemicals) and titanium disulphide (TiS_2 , 99.8%, Wako Pure Chemical Industries) were used as the starting materials. Appropriate amounts of Li_2S and TiS_2 were weighed and mixed, and the mixture (1.5 g) was placed into a zirconia pot (45 mL) along with 500 zirconia balls (4 mm in diameter). The pot was then placed in an argon-filled glove box. The rotation speed of ball milling was fixed at 510 rpm.

The XRD patterns of the synthesised samples were recorded using an X-ray diffractometer (Rotaflex RU-200B/RINT, Rigaku). Prior to the measurements, the samples were covered with Kapton® film in an argon-filled glove box to prevent exposure to air. The electrochemical cells used to test the samples were also constructed in an argon-filled glove box. The working electrodes were prepared from Li_2TiS_3 (10 mg), acetylene black (2 mg), and polytetrafluoroethylene (PTFE) powder (0.7 mg). A 1 M solution of LiPF_6 in a 50:50 (by volume) mixture of EC and DMC (Tomiyama Pure Chemical Industries Ltd.) was used as the electrolyte. The counter electrode consisted of a Li foil disk (15 mm diameter, 0.2 mm thickness). The electrochemical measurements were performed at 30°C using a charge-discharge unit (TOSCAT-3100, Toyo System) at a current density of 10 mA g^{-1} between 1.5 and 3.0 V. The all-solid-state cells were constructed as follows. Li_2TiS_3 , the glass electrolyte $70(0.75\text{Li}_2\text{S} \cdot 0.25\text{P}_2\text{S}_5) \cdot 30\text{LiI}$, and acetylene black (AB) were mixed in a weight ratio of 60:30:10 in an agate mortar, and the mixture was used to prepare the positive-electrode material. The glass electrolyte $\text{Li}_2\text{S} \cdot \text{P}_2\text{S}_5 \cdot \text{LiI}$, which has an ionic conductivity of more than $10^{-3} \text{ S cm}^{-1}$ ^{18–19}, was used as the solid electrolyte. A lithium-indium alloy was used to make the counter electrode. Bilayered pellets consisting of the positive-electrode material (10 mg) and the glass electrolyte (70 mg) were pressed under a pressure of 360 MPa (diameter = 10 mm). Pieces of indium foil (thickness = 0.3 mm, diameter = 9 mm) and lithium foil (thickness = 0.1 mm, diameter = 8 mm) were then placed on top of the bilayer pellets by pressing them all together under a pressure of 100 MPa. The pellets were pressed using two stainless steel rods, which were used as current collectors for both the positive electrode and the negative

electrode. All the processes for preparing the electrochemical cells were performed in a dry Ar-filled glove box ($[H_2O] < 1$ ppm).
