While biogeochemical and physical processes in the Southern Ocean are thought to be central to atmospheric CO₂ rise during the last deglaciation, the role of the equatorial Pacific, where the largest CO₂ source exists at present, remains largely unconstrained. Here we present seawater pH and pCO₂ variations from fossil *Porites* corals in the mid equatorial Pacific offshore Tahiti based on a newly calibrated boron isotope paleo-pH proxy. Our new data, together with recalibrated existing data, indicate that a significant pCO₂ increase (pH decrease), accompanied by anomalously large marine ¹⁴C reservoir ages, occurred following not only the Younger Dryas, but also Heinrich Stadial 1. These findings indicate an expanded zone of equatorial upwelling and resultant CO₂ emission, which may be derived from higher subsurface dissolved inorganic carbon concentration.

Understanding the past condition of the surface ocean carbonate system and air-sea CO₂ exchange is crucial to projecting future changes in the carbon cycle under ongoing anthropogenic global warming and ocean acidification. Atmospheric CO₂ concentration increased by as much as 80 μatm during the last deglaciation, with ~50 μatm released during Heinrich Stadial 1 (HS1, from 17.5 to 14.6 kyr), followed by an additional ~30 μatm during the Younger Dryas (YD, from 12.9 to 11.7 kyr) (ref. 1). While the Southern Ocean is generally considered to be central to the deglacial CO₂ rise^{2–9}, the contribution from other oceanic regions remains relatively uninvestigated^{10–13}. Information on the partial pressure of CO₂ (pCO₂) is needed to directly constrain past air-sea CO₂ exchange, and this can be reconstructed from boron isotopes (δ¹¹B), a marine carbonate pH proxy^{14,15}. Regions where surface seawater CO₂ is out of equilibrium with the atmosphere are ideal for such studies, and the equatorial Pacific is particularly well suited because it represents the largest global CO₂ source at present (e.g. ref. 16). Corals broadly distributed in tropical to subtropical areas constitute excellent high-resolution geochemical archives for paleo-CO₂ studies because they may be precisely radiogenically dated (U-series)^{3,17}, unlike foraminifers that are affected by uncertainty in radiocarbon reservoir age (R).

Two previous studies have attempted to constrain equatorial Pacific CO₂ changes. Palmer and Pearson¹⁰ showed increased CO₂ emission during the last deglaciation in the western equatorial Pacific (WEP) from δ¹¹B measurements on the planktonic foraminifer (*Globigerinoides sacculifer*) in a sediment core recovered from offshore Papua New Guinea (ERDC-92, Fig. 1a). Further east, Douville *et al.*¹¹ performed δ¹¹B on fossil corals from the Marquesas (9.5°S 139.4°W, Fig. 1a) and also demonstrated increased CO₂ release at the end of the YD. However Douville *et al.*¹¹ did not observe a significant CO₂ release during HS1, complicating interpretation of the equatorial contribution to deglacial atmospheric CO₂ rise. Integrated Ocean Drilling Program Expedition 310 (IODP Exp. 310)¹⁸ drilled the outer reef slope at Tahiti (17.6°S 149.5°W, Fig. 1a) recovering fossil corals from an open ocean environment spanning HS1, which enable us to assess the issue.

Results

δ¹¹B-pH calibration. This study establishes a new empirical δ¹¹B-pH calibration utilizing, for the first time, anthropogenic ocean acidification. Empirical calibration is needed to overcome the observed offsets from a theoretical δ¹¹B-pH curve in culture experiments for zooxanthellate corals^{14,15}. (pH is reported using the total hydrogen scale, hereafter pH for simplicity). There are two primary approaches to overcoming the reported offsets. One is an empirical approach¹⁴ that assumes constant offsets in measured and theoretical δ¹¹B (“offset a,” see Methods), while the other is an observational approach¹⁵ that considers potential pH modification by calcifiers.

Figure 1 | Sea surface pCO₂ in the equatorial Pacific and vertical sections of the South Pacific. (a) Equatorial Pacific locations discussed in the text with sea surface pCO₂ for the reference year AD 2000 in which red and blue represent CO₂ sources and sinks, respectively¹⁶. Vertical sections from 60°S to 30°N of (b) oxygen, (c) silicate, (d) DIC, and (e) Δ¹⁴C. All data are downloaded and plotted using Ocean Data View software, version 4.5.5 (ref. 60). Inverted black triangles show locations of Tahiti and Marquesas. The white star and diamond in **e** indicate the locations of cores MV99-MC99/GC31/PC08 (refs. 36,43) and V21-31 (ref. 42), respectively.

The potential for pH-modification is of great concern for δ¹¹B-based reconstruction of pH due to the implications for atmospheric pCO₂ calculation. Such a phenomenon is consistent with indirect pH measurements of internal calcification fluid using pH sensitive dye that suggests a higher pH than ambient seawater, creating better conditions for calcification¹⁹. A ‘ΔpH’ concept in the δ¹¹B-pH calibration that reflects pH differences in seawater (pH_{SW}) and internal calcification fluid has been proposed¹⁵, however usage of this proposed relationship to calibrate δ¹¹B of modern *Porites* spp. from Tahiti and Marquesas resulted in unrealistically high values (e.g. ~8.34 in AD 1991), well above reported estimates (e.g. refs. 20,21). Therefore the present study employs the empirical equation¹⁴ here (see Methods).

Ocean acidification was estimated from a combination of *in situ* fCO₂ values in the surface ocean, atmospheric CO₂ concentration directly measured at the Mauna Loa observatory in Hawaii since AD

1960 (ref. 22), and CO₂ concentrations within bubbles trapped in an Antarctic ice core²³ (Figs. 2, S1–S4; Supplementary Methods). These data were then fit to the previously reported δ¹¹B measurements of *Porites* spp. (refs. 11,24), which are for the years AD 1991, 1950, and 1700 (Fig. 2, see Methods and Supplementary Methods for details of the δ¹¹B-pH calibration and pH estimation since the Industrial Revolution).

pH and pCO₂ reconstruction. Using our revised calibration, we reconstructed pH from our new δ¹¹B measurements on Tahitian corals, as well as from previously reported data¹¹ from both the Marquesas and Tahiti, and the overall result is consistent with the WEP foraminifer δ¹¹B variations¹⁰ (Fig 3a and b). The oldest coral sample, dated to 20.7 ka BP during the last glacial maximum (LGM), exhibits a relatively high pH (8.26). From 15.5 to 9.0 ka BP, pH is generally constant within uncertainty (8.15–8.22) and consistent

Figure 2 | Measured pCO_2 from Mauna Loa²² and Law Dome ice core²³ (red and blue lines) and estimated pH variation at Tahiti (black line). Green triangles are newly calibrated pH from previously reported $\delta^{11}B$ of modern corals from Tahiti and Marquesas^{11,24} (Table S1). Estimated pH from the AD 1700 Marquesas coral was scaled by 0.04 to correct for offset from Tahitian coral values. Error bars are 2σ .

with the preindustrial value of 8.20. Four notable pH excursions are associated with HS1 and the YD. Two of our samples exhibit anomalously low pH at the end of HS1 (8.13 at 15.15 ka and 8.09 at 14.99 ka BP), in addition to those at end of the YD at the

Figure 3 | Deglacial $\delta^{11}B$, pH and pCO_2 variability in the equatorial Pacific. (a) Reported $\delta^{11}B$ values of planktonic foraminifera with 2σ uncertainty from ERDC-92 (ref. 10). Age model is from the original publication. (b) *In situ* pH reconstructed from $\delta^{11}B$ of fossil *Porites* spp. using our new calibration. Red and green circles are from Tahiti by this study and Douville *et al.*¹¹, respectively. Blue circles are from Marquesas by Douville *et al.*¹¹ after correction by +0.04 pH units. (c) Derived pCO_2 of surface water around equatorial South Pacific Ocean (same colors as b) and atmospheric pCO_2 on the GICC05 timescale¹. All error bars are 2σ . YD, Younger Dryas; B/A, Bølling/Allerød; ACR, Antarctic Cold Reversal; HS1, Heinrich Stadial 1; LGM, Last Glacial Maximum.

Marquesas¹¹. The low pH following HS1 had been previously undetected at this location. Calculation of pCO_2 (see Methods) reveals deglacial values significantly above those of the atmosphere (Figs. 3c and 4a). Conversely, ΔpCO_2 during last glacial and the early Holocene was nearly zero, suggesting air-sea CO_2 equilibrium.

Results from a different portion of the same 14.99 ka BP coral sample deviate by as much as 1.4‰, which corresponds to 0.11 in pH and 100 μatm in pCO_2 (310-M0024A-11R-1W_77-90 and 310-M0024A-11R-1W_60-75, Table S1). Considering the average ~ 4 year temporal resolution of each sample, these excursions occurred abruptly and persisted for several years, which differs from modern observations that show no clear interannual or decadal variability (Supplementary Methods, Fig. S1). This enhanced variability, which is also observed in Sr/Ca derived SST results from another *Porites* colony recovered from IODP Exp. 310 (ref. 25), may relate to Tahiti's location at the rim of equatorial upwelling cell (Fig. 1a). Taken together, pCO_2 (pH) records indicate that the equatorial Pacific became a larger CO_2 source during the last deglaciation with excursions at the end of HS1 and the YD.

Marine ^{14}C reservoir age compilation. Compiled marine ^{14}C reservoir ages (R) throughout the equatorial Pacific resemble pCO_2 variability (see Methods; Figs. 4 and S5; Table S2). Larger and more variable values of R are evident in Tahiti during HS1 and the YD, and enhanced R variability is also seen in the Marquesas (Figs. 4 and S5). Paterne *et al.*²⁶ sub-sampled different parts in the same fossil coral skeleton and analyzed both ^{14}C and U/Th. They observed no difference in U/Th dates, but a much larger difference in ^{14}C .

Figure 4 | Differences between modern and deglacial pCO_2 and R (ΔpCO_2 and R_{diff}). The last deglaciation is characterized by larger and more variable pCO_2 and R values. (a) Atmosphere-ocean ΔpCO_2 based on Tahiti and Marquesas corals and Antarctic ice core¹. Figure legend is same as Fig. 3. (b) R_{diff} around the equatorial Pacific Ocean calculated from fossil corals (red: offshore Tahiti; orange: reef crest of Tahiti barrier reef²⁸; blue: Marquesas²⁶; light blue: Kiritimati²⁹; black: Mururoa²⁸). Horizontal dashed lines represent $\Delta pCO_2 = 0$ and $R_{diff} = 0$.

Possibilities of either a diagenetic alteration or a change in R were suggested. The latter is more probable because a large variation in R is also suggested from Vanuatu coral at 11.7–12.4 ka (~400 years; during the YD, ref. 27).

Though reported R_{diff} (difference between calculated R and modern R ; see Methods) data around the upwelling zone during the LGM are sparse, calculations with the new Lake Suigetsu datasets²⁸ suggests no substantial change in R (see Methods; Figs. 4 and S5). This implies that the CO_2 exchange rate in the surface equatorial Pacific during the last glacial was almost the same as present, which supports the above-mentioned observation that $\Delta p\text{CO}_2$ is essentially equivalent to zero and indicates that anomalous R values are limited to the last deglaciation.

Discussion

$p\text{CO}_2$ variability in subtropical oligotrophic water can be explained by mixing of water masses that exhibit distinctly different dissolved inorganic carbon (DIC) concentrations. A southward migration of the intertropical convergence zone (ITCZ) that partly controls thermocline depth is hypothesized during Heinrich Events including HS1 and the YD (e.g. ref. 29). At present, the ITCZ does not seem to affect surface $p\text{CO}_2$ variability (Fig. 1a), and if it is displaced southward, the locus of equatorial upwelling remains at the equator due to the influence of inter-hemispheric asymmetry of Coriolis force (e.g. refs. 30,31). Enhanced upwelling (shallower thermocline, La Niña-like conditions) or increased subsurface DIC concentration are more likely to drive $p\text{CO}_2$ variability based on sedimentary evidence from the equatorial Pacific for higher nutrient content, e.g., enhanced biogenic opal export production and lower stable carbon isotopes ($\delta^{13}\text{C}$) (TT013-PC72, ODP Site 1240 and TR163-19)^{32–35} (Fig. 1a). Semi-conservative radiogenic neodymium isotopes (ϵNd) from sediment cores at the eastern equatorial Pacific (EEP) (ODP Site 1240) and off Baja California (MV99-MC99-GC31/PC08) indicate stronger subsurface water transport from the south^{33,36} (Fig. 1). Covariation of geochemical properties between the Southern Ocean and the equatorial Pacific suggest a subsurface connection during the last deglaciation (e.g. refs. 32–38). Thus, $p\text{CO}_2$ variability may be explained by an increase in DIC in the upwelled, subsurface water masses as opposed to physical processes alone.

Water mass subduction along the subantarctic front, mainly off Chile³⁹, forms Subantarctic Mode Water (SAMW) and Antarctic Intermediate Water (AAIW) that upwells at the equatorial Pacific via the Equatorial Undercurrent (EUC) (Fig. 1). SAMW and AAIW are characterized by higher/lower concentrations of oxygen/silicic acid (Fig. 1b,c). It is suggested that the abyssal DIC reservoir around the Southern Ocean increased during the last glacial period^{6–8,40}, which would have contributed to lower atmospheric $p\text{CO}_2$. Carbon dioxide was released to the surface through deep ocean ventilation during HS1 and the YD (refs. 2–9), however export production was insufficient to fully compensate the increased carbon flux⁴¹. This is consistent with residual radiocarbon content ($\Delta^{14}\text{C}$) of intermediate water at the EEP (V21–30)⁴² and off Baja California (MV99-MC99-GC31/PC08)⁴³ that indicates anomalously older water was incorporated into SAMW/AAIW (Fig. 1), as well as with depleted $\delta^{13}\text{C}$ of surface and lower thermocline dwelling foraminifers from sediment cores at both equatorial (TT013-PC72, ODP Site 1240 and TR163-19) and South Pacific sites^{32–35,37,38}. Moreover, enhanced export production of biogenic opal suggest more silicic acid was transported via the EUC to thermocline water at the equatorial Pacific (V19-30 and TT013-PC72) without being consumed completely within the Southern Ocean^{4,35,41}. Stronger Ekman transport in association with sea ice retreat and a poleward shift of southern westerlies is suggested to be a driver^{4,5}.

A similarity between R and $p\text{CO}_2$ variability during the last deglaciation supports an interpretation that older DIC was incorporated to subtropical surface water through mixing with SAMW/AAIW,

though, contrary evidence comes from the current formation sites off Chile⁴⁴ and New Zealand⁶. However, a key sediment record off Chile was recently reevaluated, and the new interpretations indicate stronger upwelling and subsequent larger R in surface water in the Southern Ocean⁹, which agrees well with our interpretation. Yet, further work is still needed to fully understand both the physical and biogeochemical dynamics in the Southern Ocean and the equatorial Pacific².

Positive $\Delta p\text{CO}_2$ indicates CO_2 flux from the ocean to the atmosphere. Previous studies^{10,11} indicated that the equatorial Pacific contributed to deglacial CO_2 rise, however the timing of anomalously higher $p\text{CO}_2$ events recorded in radiogenically dated fossil corals do not systematically correspond to those of atmospheric CO_2 rise recovered from Antarctic ice core on the GICC05 timescale¹ (Figs. 3 and 4). Moreover our new calibration reveals a modest CO_2 emission continued through the Bolling/Allerød/Antarctic Cold Reversal when no atmospheric CO_2 increase is observed (Figs. 3 and 4). Though we demonstrate that the equatorial Pacific became a larger CO_2 source during the last deglaciation, it is too early to conclude its exact contribution to atmospheric CO_2 rise. The Southern Ocean is suggested to be central in CO_2 degassing^{4–9} and the contribution of the terrestrial biosphere should be further evaluated⁴⁵. More evidence spanning the YD and the early part of HS1, in particular the sharp rise in atmospheric CO_2 and the sudden drop of $\delta^{13}\text{C}$ of CO_2 (refs. 1,46), as well as more spatial coverage is needed.

Methods

$\delta^{11}\text{B}$ analyses. The $\delta^{11}\text{B}$ values of fossil *Porites* spp. were measured following the protocol of Ishikawa and Nagaishi⁴⁷. Fossil corals were screened for diagenetic alteration with X-ray diffraction and geochemical analyses, as well as visual using a Scanning Electron Microscope⁴⁸. Bulk sampling was conducted along the growth axis, and time resolution of each sample is several years (1–8 years) depending on growth rate of each coral⁴⁸. Typically 6 mg of carbonate was used for $\delta^{11}\text{B}$ measurement. After removals of organic matter using 30% H_2O_2 for ~12 hours, boron was purified by cation and anion exchange using AG 50 W X12 and 1-X4 resin (Bio-Rad, USA) and then $\delta^{11}\text{B}$ were measured using the positive polarity thermal ionization mass spectrometer (P-TIMS; Thermo Finnigan TRITON) installed at Kochi Core Center, Japan Agency for Marine-Earth Science and Technology. All reported $\delta^{11}\text{B}$ values are the mean of duplicate analyses (Table S1). Repeated analysis of the JCP-1, carbonate standard provided by Geological Survey of Japan yielded $24.21 \pm 0.18\text{‰}$ (2σ , $n = 18$), which is the finest precision to date⁴⁷. Differences between the duplicates are 0.08‰ on average with the largest one of 0.28‰ (Table S1), which is within the measurement uncertainty of JCP-1. We conservatively report $\pm 0.18\text{‰}$ as the analytical uncertainty of our $\delta^{11}\text{B}$ measurements.

$\delta^{11}\text{B}$ -pH calibration and $p\text{CO}_2$ calculation. First, the analytical procedure-specific isotopic offset⁴⁹ was corrected using the equation below (modified after Zeebe & Wolf-Gladrow⁵⁰) in order to reduce inter-laboratory offsets in reported $\delta^{11}\text{B}$ values,

$$\delta^{11}\text{B}_{\text{carbonate-corrected}} = \delta^{11}\text{B}_{\text{SW-stacked}} + \frac{\delta^{11}\text{B}_{\text{SW-stacked}} + 10^3}{\delta^{11}\text{B}_{\text{SW-measured}} + 10^3} * (\delta^{11}\text{B}_{\text{carbonate-measured}} - \delta^{11}\text{B}_{\text{SW-measured}}) \quad (1)$$

where $\delta^{11}\text{B}_{\text{carbonate-corrected}}$ is the boron isotopic value of carbonate after correction and $\delta^{11}\text{B}_{\text{SW-stacked}}$ is the global average $\delta^{11}\text{B}$ of seawater. We used the recommended value of 39.61‰ for $\delta^{11}\text{B}_{\text{SW-stacked}}$ (ref. 49). $\delta^{11}\text{B}_{\text{carbonate-measured}}$ and $\delta^{11}\text{B}_{\text{SW-measured}}$ are $\delta^{11}\text{B}$ of carbonate samples and of seawater measured in different laboratories. Without performing inter-laboratory correction of JCP-1, results of Douville *et al.*¹¹ and this study differ by 0.25‰ , equivalent to ~0.03 pH units. After the correction using the reported value of $\delta^{11}\text{B}_{\text{SW-measured}}$ (refs. 11,47), the difference improved to be 0.07‰ , indicating that correction should be performed.

After the correction, the empirical calibration equation reported by Hönisch *et al.*¹⁴ was utilized. In this equation, the vital offset 'a' and fractionation factor ' α_{3-4} ' that yield the lowest e_{rms} (root-mean square error) is determined.

$$\text{pH} = \text{pK}_B - \log \left(\frac{-(\delta^{11}\text{B}_{\text{SW-stacked}} - \delta^{11}\text{B}_{\text{carbonate-corrected}} - a)}{\delta^{11}\text{B}_{\text{SW-stacked}} - \epsilon_{3-4} * (\delta^{11}\text{B}_{\text{carbonate-corrected}} + a) - 10^3 * (\alpha_{3-4} - 1)} \right) \quad (2)$$

Three previously reported $\delta^{11}\text{B}$ values for modern *Porites* spp. from Tahiti and Marquesas were fit to estimated pH at AD 1991, 1950 and 1700 (refs. 11,24) (Fig. 2, Table S1). In the calibration 'a' was determined as '−6.0' when we chose recently reevaluated α_{3-4} of '1.0272' (ref. 51). When this calibration was conducted, both 'a' and ' α_{3-4} ' were allowed to vary freely, and the resultant α_{3-4} with the lowest e_{rms} was very close to that of Klochko *et al.*⁵¹ rather than the previously accepted value of Kakihana *et al.*⁵² Thus we used Klochko's fractionation factor. pH was calculated from

both previously reported and newly obtained $\delta^{11}\text{B}$ values considering a local difference of seawater pH between Tahiti and Marquesas (see Supplementary Methods for details).

pCO_2 was further calculated from obtained pH values from $\delta^{11}\text{B}_{\text{carbonate-corrected}}$ using CO2SYS program under assumptions of constant temperature, salinity and total alkalinity (see also Supplementary Methods for details). The $\delta^{11}\text{B}$ values of *G. sacclifer*¹⁰ are not included here due to large uncertainties in the $\delta^{11}\text{B}$ -pH calibration (e.g. refs. 12,15).

R compilation. Published ^{14}C (radiocarbon years) and U/Th ages of fossil coral samples obtained during IODP Exp. 310 were compiled in order to calculate residual radiocarbon activities ($\Delta^{14}\text{C}$) and R. We verified via IODP sample ID and core photographs¹⁸ that the exact same samples were selected (Table S2). In some cases different portion of the skeleton of the same coral was dated. Given that lifetimes of coral are generally less than several decades, temporal gaps derived from subsampling are negligible in calculations of $\Delta^{14}\text{C}$ and R. We did not use ^{14}C ages from either microbialite (carbonate created by bacteria) or encrusting coralline algae from equivalent down-core depths due to a possibility of post-depositional growth (for details, see ref. 53). Calculation was done according to equations (3) and (4) where ^{14}C -age is an original radiocarbon data before a local R correction^{54,55}.

$$\Delta^{14}\text{C}_{\text{marine}} = \left(\frac{e^{-\frac{^{14}\text{C}_{\text{age}}}{8033}}}{e^{-\frac{(U/\text{Th})_{\text{age}}}{8266}}} - 1 \right) * 10^3 \quad [\text{‰}] \quad (3)$$

$$R = 8033 * \ln \left(\frac{\frac{\Delta^{14}\text{C}_{\text{atm}}}{10} + 1}{\frac{\Delta^{14}\text{C}_{\text{marine}}}{10} + 1} \right) = ^{14}\text{C}_{\text{age(marine)}} - ^{14}\text{C}_{\text{age(atm)}} \quad (4)$$

Atmospheric ^{14}C ($\Delta^{14}\text{C}_{\text{atm}}$) from INTCAL09 (ref. 56) was used to calculate R. Samples that span 29–30 ka BP were calculated using the recently published Lake Suigetsu $\Delta^{14}\text{C}_{\text{atm}}$ dataset²⁸, since as much as ~100‰ offsets are observed between INTCAL09 in this interval (Fig. S5a). Southon *et al.*⁵⁷ points out that the INTCAL09 curve heavily relies on Cariaco Basin varve sediment data beyond the dendro-chronological limit (>12.55 ka BP) and has deficits during the YD and HSI due to changes in local R in the equatorial Atlantic. Specifically, a difference during 15.5–17.0 ka BP is apparent, however it does not affect our calculation since there are no samples that span this interval (Fig. S5). Other ^{14}C and U/Th datasets for fossil corals from the equatorial Pacific islands were also used to calculate R including Tahiti⁵⁸, Marquesas⁵⁹, Kiritimati⁵⁹ and Mururoa⁵⁸ (Figs. 1, 4, and S5b). R_{diff} denotes differences between calculated R and modern R (235 ± 110 for Tahiti⁵⁶, 390 ± 60 for Marquesas⁵⁹, 335 ± 100 for Kiritimati⁵⁶, 300 ± 100 for Mururoa⁵⁸), thus it differs from ΔR that conventionally represents local ^{14}C reservoir age. We estimate that the accumulated uncertainty in the R_{diff} calculation are the sum of errors in ^{14}C dating, U/Th dating, and modern R (Fig. S5b; Table S2).

Acknowledgments

We thank the IODP Exp. 310 Science Party, in particular G. Camoin, Y. Iryu and D. McInroy, as well as W. Hale, U. Röhl, A. Wülbers, and all the staff of the Bremen Core Repository. We would like to thank J. Matsuoka and K. Nagaishi for technical support. Our gratitude is also extended to M. Inoue, Y. Miyairi, M. Becchaku, and S. Yoshinaga for laboratory assistance. This study was partly supported by the JSPS NEXT program GR031 and grant number 26247085 to Y.Y., grant number 24340127 to T.I. and Research fellowships for young scientists to K.K.

Author contributions

Y.Y. designed the study and obtained samples. K.K. and T.I. measured coral boron isotope ratios. A.S. prepared samples. S.O. performed the statistical analysis of the data. K.K., Y.Y., T.I., S.O. and A.S. contributed to the interpretation and the preparation of the final manuscript.
