com)Morphology-modulation of SnO₂
Hierarchical Architectures by Zn Doping
for Glycol Gas Sensing and
Photocatalytic ApplicationsQinqin Zhao¹, Dianxing Ju², Xiaolong Deng¹, Jinzhao Huang¹, Bingqiang Cao² & Xijin Xu¹¹School of Physics and Technology, University of Jinan, 336 West Road of Nan Xinzhuang, Jinan, 250022, Shandong Province, Peoples Republic of China, ²School of Materials Science and Engineering, University of Jinan.

The morphology of SnO₂ nanospheres was transformed into ultrathin nanosheets assembled architectures after Zn doping by one-step hydrothermal route. The as-prepared samples were characterized in detail by various analytical techniques including scanning electron microscopy (SEM), transmission electron microscopy (TEM), X-ray diffraction (XRD), and nitrogen adsorption-desorption technique. The Zn-doped SnO₂ nanostructures proved to be the efficient gas sensing materials for a series of flammable and explosive gases detection, and photocatalysts for the degradation of methyl orange (MO) under UV irradiation. It was observed that both of the undoped and Zn-doped SnO₂ after calcination exhibited tremendous gas sensing performance toward glycol. The response ($S = R_a/R_g$) of Zn-doped SnO₂ can reach to 90 when the glycol concentration is 100 ppm, which is about 2 times and 3 times higher than that of undoped SnO₂ sensor with and without calcinations, respectively. The result of photocatalytic activities demonstrated that MO dye was almost completely degraded (~92%) by Zn-doped SnO₂ in 150 min, which is higher than that of others (MO without photocatalyst was 23%, undoped SnO₂ without and with calcination were 55% and 75%, respectively).

As one of the most important classes of materials, metal oxide semiconductors are presenting themselves in various areas of science and technology, due to their desirable morphologies and distinct structures^{1,2}. SnO₂, a typical n-type semiconductor with a wide band gap (3.6 eV)^{3–5}, has been widely investigated with many applications such as gas sensors^{6–9}, solar cells¹⁰, lithium batteries¹¹, catalysis^{12–15}, and transparent conductive electrodes¹⁶, because of its unique optical, catalytic, and electrical properties and high chemical stability. It has been reported that the performances of SnO₂ nanomaterials are greatly affected by their morphology, structure and surface area¹⁷. Therefore, it is believed that their advanced nanostructured materials with different dimensionalities would offer good opportunities to explore new physical and chemical applications including gas sensors and photocatalysis. Recently, Guo et al.¹⁸ reported that the sensor, fabricated by 3D SnO₂ microstructures assembled by porous nanosheets through hydrothermal synthesis, exhibited good response-recovery performance, high sensitivity and excellent long-term stability for ethanol gas. Dai et al. synthesized flower-like SnO₂ microstructures which exhibited higher photoactivity (about 2.2 times) than granular SnO₂ for the degradation of RhB dye¹⁹. These structural features can improve both the sensing performance and the photocatalytic degradation rate. In this view, the more attention should be paid to the design and synthesis of hierarchical SnO₂ nanomaterials.

In order to satisfy the increasing demands for the photocatalysts or gas sensors working under harsh and complicated conditions, many efforts have been made to improve the performance of SnO₂ materials such as doping^{20–23}, adding catalysts^{24–26}, and constructing the heterojunctions^{27,28}. Among these methods, doping has been proposed to be a facile efficient way to modulate their properties. In particular, the previous reports demonstrated that the morphologies and properties of SnO₂ could be modified by Zn doping^{29–32}. This could be attributed to the facile substitution of Sn ions by Zn ions due to the similar ion radius of Zn²⁺ and Sn⁴⁺ (Zn²⁺ 0.074 nm, Sn⁴⁺ 0.071 nm), which may produce more oxygen vacancies for charge compensation and further enhance the performance of SnO₂. Thus, it is expected that Zn-doped SnO₂ hierarchical nanostructures will provide excellent gas sensing and photocatalytic properties.

Figure 2 | (a) and (e) TEM images of undoped and Zn-doped SnO₂; (b, f) HRTEM images of undoped and Zn-doped SnO₂ with their SAED pattern (c, g); (d, h) EDX spectra of undoped and Zn-doped SnO₂. Undoped (S1 600°C) and Zn-doped SnO₂ (S2 600°C). The peaks of Cu and C observed in the EDX spectrum are from carbon-coated copper grids.

Here, the Zn-doped SnO₂ hierarchical nanostructures were synthesized by one-step hydrothermal process, which are composed of a number of nanosheets with the thickness of about 30 nm. The as-prepared samples were applied to the glycol detection and the photocatalytic degradation of methyl orange (MO) under UV irradiation. The results indicated that Zn-doped SnO₂ hierarchical nanostructures had better glycol gas response and photocatalytic activity than undoped SnO₂ nanostructures.

Methods

Synthesis of undoped and Zn-doped SnO₂ hierarchical nanostructures. All chemicals were of analytical grade reagents and used without any further purification. A typical synthesis process was as follows: 6 mM of NH₄F was dissolved in 50 ml of deionized water under vigorous magnetic stirring, followed by adding 2 mM of SnCl₂·2H₂O and 2 mM of ZnCl₂ into the above solution with the assistance of ultrasonication. The mixed solution was then transferred into a 100 ml Teflon-lined stainless steel autoclave, and kept at 180°C for 16 h in order to obtain the precipitates.

Figure 3 | Raman spectrum of undoped (S1 600°C) and Zn-doped SnO₂ (S2 600°C).

Then, the autoclave cooled to room temperature naturally. The obtained products were collected and washed with deionized water and ethanol several times, respectively, and then dried in air at 60°C for 12 h. Finally, the products were annealed at 600°C for 2 h, named as S2. The undoped SnO₂ was obtained by the same process except the addition of ZnCl₂, named as S1. The undoped SnO₂ sample without calcination was named as S0.

Material Characterizations. The compositions and morphologies of the as-prepared samples were characterized by a field emission scanning electron microscope (FESEM, FEI QUANTA FEG250) equipped with an energy dispersive x-ray spectroscopy (EDS, INCA MAX-50) and a high-resolution transmission electron microscope (Tecnai G2 F20). The crystal structures of the samples were analyzed by X-ray diffraction (XRD, D8-Advance, Bruker) with Cu K α radiation and Raman spectrometer (Renishaw inVia) in the range from 200 cm⁻¹ to 1000 cm⁻¹ at room temperature. The average pore size, pore volume, and specific surface area of the samples were examined through measuring N₂ adsorption-desorption isotherm with a Micromeritics ASAP2020 apparatus.

Fabrication and Gas-Sensing measurements. Gas sensors were fabricated as follows: The as-prepared sample was mixed with the deionized water to form a paste, and then it was coated onto an Al₂O₃ tube by a small brush to form a thick film between two parallel Au electrodes, which had been previously printed on the tube. A heater of Ni-Cr coil was inserted into the Al₂O₃ tube to keep the sensor at the operating temperature. The gas sensor properties were measured by a gas sensing test system (WS-30A, Weisheng Electronics, Zhengzhou, China) with a test voltage of 5 V under laboratory conditions (30% $\pm$ 10% RH, 23 $\pm$ 1°C). The devices were put into an airproof test box and tested by a static process in a test chamber. A given amount of the target gas was injected into the test chamber, when the response reached a constant value, the upper cover of the test chamber was removed and the sensor began to recover in air. The response of the sensor was defined as $S = R_a/R_g$ for target gas, where R_a and R_g are the sensor resistance in air and in target gas, respectively.

Photocatalytic Measurements. The photocatalytic activity of the samples was investigated by measuring the degradation of methyl orange (MO) under UV light (generated by a 500 W high pressure mercury lamp). Typically, 30 mg of as-prepared sample was added to the aqueous solution of MO dye (50 ml, 20 mg/L) with stirring in the dark for 30 min to ensure the absorption/desorption equilibrium. Then, the suspension was exposed to UV light irradiation whilst stirring. At given irradiation time intervals, concentrations of MO were monitored with a TU-1901 UV-vis spectrophotometer by measuring the absorbance at 464 nm during the degradation process.

Results and discussion

Representative morphologies and structures of the as-obtained SnO₂ nanostructures, revealed by field-emission scanning electron microscopy (SEM), are shown in Figure 1. The surface morphologies of undoped SnO₂ (S1) are shown in Figure 1(a, b). It can be seen that the products are mostly spherical-like structures with a relatively rough surface, which is consisted of SnO₂ nanorods. The morphologies of the Zn-doped SnO₂ (S2) are shown in Figure 1(c, d). Compared with the undoped sample, the products are composed of SnO₂ nanosheets, which may be attributed to the induced growth of Zn²⁺ ions, as

Figure 4 | Nitrogen adsorption-desorption isotherms and pore size distribution curves (inset) of S1 (SnO₂ 600°C) and S2 (Zn-doped SnO₂ 600°C).

shown in Figure 1(e). The peak of Zn can be clearly observed in the spectrum and the content ratio of Zn and Sn is about 1.60:10.93, shown in the insert table. Figure 1(f) shows the typical XRD patterns of the as-prepared undoped (S1) and Zn-doped SnO₂ (S2) architectures. All the diffraction peaks could be well indexed to the tetragonal rutile structure of SnO₂, which was consistent with the standard data file (JCPDS file no. 41-1445). No obvious characteristic peaks are observed for the impurities. Additionally, the diffraction peaks of the Zn-doped SnO₂ tend to become slightly broader from Figure 1(f), which could be attributed to the size effect of the crystals. The mean grain size of undoped and the Zn-doped SnO₂ were calculated to be 29.3 nm and 22.6 nm, respectively, using the Debye-Scherrer formula, $D = 0.89\lambda / (\beta \cos \theta)^{33}$, where λ is the X-ray wavelength, θ is the Bragg diffraction angle and β is the peak full-width at half maximum.

The morphologies and microstructures of the samples S1 (SnO₂) and S2 (Zn-doped SnO₂) were further studied by TEM, as shown in Figure 2. From Figure 2(a), we get to know that the undoped SnO₂ (S1) is mainly comprised of spherical-like structures constructed by nanorods with a diameter of 20–30 nm and a length up to one hundred nanometers. This is in consistent with the SEM images in Figure 1(a, b). The HRTEM image is shown in Figure 2(b), in which the interplanar distances are 0.34 nm and 0.27 nm, respectively, matching well with (110) and (101) planes of rutile SnO₂. The selected area electron diffraction (SAED) pattern taken from the corresponding microspheres suggests a polycrystalline structure of as-prepared sample, as shown in Figure 2(c). The peak of Sn and O can be clearly observed in the spectrum from EDX spectrum (Figure 2(d)) for the undoped SnO₂ revealing a purity phase. The peaks of Cu and C observed in the spectrum are attributed to the carbon-coated copper grids.

Compared with the undoped SnO₂, the Zn-doped SnO₂ are mainly composed of SnO₂ nanosheets, as shown in Figure 2(e). The HRTEM image (Figure 2(f)) shows that the lattice fringes of the Zn-doped SnO₂ nanostructures are 0.34 and 0.27 nm, which correspond to the (110) and (101) lattice planes of SnO₂, respectively, as shown in Figure 2(g). The SAED pattern indicates that the nanosheet is of polycrystalline structure composed of nanoscaled particles. Figure 2(h) shows the EDX spectrum of the Zn-doped SnO₂, in which the peak of Zn can be clearly observed in the spectrum, which is corresponding to the XRD pattern of Zn-doped SnO₂. Furthermore, it can be seen from the SEM and TEM images that SnO₂ nanorods change into nanosheets after the doping of Zn element. This evolution is ascribed to the successfully substitutional doping of Zn²⁺ ions into SnO₂ lattice with modification of local

Figure 5 | Schematic formation mechanisms of undoped (S1 600°C) and Zn-doped SnO₂ (S2 600°C).

structure³⁴. It is presumed that the modification of local structure varies the surface energy of some crystallographic planes in the prepared nanosheets, which changes the growth rate of these crystallographic planes. As can be seen in our experiment, Zn²⁺ ions in SnO₂ lattice inhibit the growth along [110] direction but permit the growth along the axis of nanorod, promoting the anisotropic growth of the nanorods³⁴. Therefore, it is believed that Zn²⁺ serves as a structure-directing agent in the growth of nanosheets.

Raman scattering is generally used to investigate the crystallinity, structural defects, and size effects of nanoscale crystallites^{35,36}. Figure 3 presents the room temperature Raman spectra of pure SnO₂ (S1) and Zn-doped SnO₂ (S2) architectures. The peaks at 630 and 774 cm⁻¹ correspond respectively to A_{1g} and B_{2g} modes, which are related to the symmetric and asymmetric stretching of Sn-O bonds, respectively^{36,37}. The peak at 475 cm⁻¹ represents E_g doubly degenerate mode, arising from the vibration mode of oxide ions. The appearance of these “classical modes” confirms the tetragonal rutile structure of Sn_{1-x}Zn_xO₂ nanostructures³⁷. Compared with undoped SnO₂, the peaks located at 630 and 774 cm⁻¹ of the Zn-doped SnO₂ Raman spectrum become broadened, which might be ascribed to the effects of oxygen deficiency and crystal distortion, caused by the introduction of Zn ions^{36,38}. In addition, such broadening of A_{1g} mode is referred to the decrease of grain size, which is consistent with the XRD results³⁹.

In order to further confirm the inner architectures, nitrogen adsorption and desorption measurements of the as-prepared products (S1 and S2) were carried out to estimate the properties, as shown in Figure 4. The specific surface area of the samples was calculated to be 51.2 and 61.8 m²g⁻¹, respectively, indicating an uptrend of the active surface after the doping of Zn. Pore size distribution curves (inset of Figure 4) are important factors for mass transport and effective surface area. The average pore size of the two samples (S1 and S2) was calculated to be 8.798 nm and 7.676 nm, respectively. The pores distributed are also observed in TEM image (Figure 2(a, e)) between the adjacent nanoparticles. It clearly indicates that the Zn-doped SnO₂ shows a higher specific surface area than that of undoped SnO₂, which might be advantageous for enhancing gas sensing performance.

Some papers have reported that Zn-doped SnO₂ would form the nanorods or nanoneedles in the ethanol-water solution using KOH or NaOH as the alkali source^{30,34}. This morphology may be attributed to the regulating function of Zn and alcohol which has been mentioned by many papers^{29,39,40}. However, when the ethanol-water solution and alkali source were replaced by water and NH₄F solution as used in our case, the morphology of the products may be changed. According to the previous reports, a possible formation mechanism is proposed, as illustrated in Figure 5^{34,41}. The tin precursor under a high temperature can be fast hydrolyzed to form Sn(OH)₂, which further decomposes to form the primary SnO₂ crystallites. After that,

the crystal nuclei of SnO₂ aggregated and grew into SnO₂ nanorods along the c-axis direction, regulated by the morphology controlling agents (NH₄F)⁴¹. Afterwards, the nanorods self-assemble into the final nanospheres to minimize their large net surface energy as illustrated in Figure 5(a). Furthermore, it has been demonstrated that the SnO₂ morphology could be successfully modulated by Zn doping^{34,42,43}. For example, Ding et al.³⁴ have demonstrated that when the molar ratio of Zn²⁺/Sn⁴⁺ exceeds 0.133 in the precursor solution, the morphology of the products can evolve into nanosheets from the nanorod. Thus, Sn²⁺ cations can be substituted when Zn²⁺ cations are introduced into the tin precursor with the same molar ratio (1 : 1), accompanying with the generation of a double ionized oxygen vacancy (V_O). Then, the charge density and the surface energy of each crystal face are changed, indicating the existence of larger polarity in the grown process of Zn-doped SnO₂ nanocrystals³⁴. This leads to a different growth rate of the various crystal faces. With the Zn²⁺ ions introduced into the solution, some Sn²⁺ ions are substituted, forming the compound nuclei under the hydrothermal conditions. Then, these nuclei grow into nanosheet structures through aggregation mechanism⁴⁴ and Ostwald ripening process⁴⁵ under the influence of the Zn²⁺. Finally, the nanosheets-assembled nanostructures are formed as shown in Figure 5(b).

The gas sensing properties of SnO₂ and Zn-doped SnO₂ sensors were first measured at different working temperature. Figure 6 exhibits the response of the sensors to 100 ppm glycol, as a function of the operating temperature in a range of 220–360°C. The optimal operating temperature for the sensors is around 240°C and the response is enhanced gradually after the process of calcination and further doped with Zn element. When the temperature is 220°C, the sensors

Figure 6 | The relationship between working temperature and response of three sensors to 100 ppm glycol gas.

Figure 7 | Response comparisons of three sensors to (a) glycol and (b) ethanol gas of different concentrations at 240°C and 320°C, respectively.

response can reach 50 (Zn-doped SnO₂ sensor) to 100 ppm glycol which is higher than that of others. With the increase of working temperature, the response further increases. Until the temperature is up to 240°C, all the sensors exhibit the maximum response and then decrease as the temperature further increase, which is due to the competing desorption of the chemisorbed oxygen^{44,46}.

Figure 7(a) shows the response curve of undoped SnO₂ and Zn-doped SnO₂ sensors to glycol of different concentrations from 5 ppm to 100 ppm at 240°C. It can be found that all the sensors responses increase with the increasing concentration of glycol, especially for the Zn-doped SnO₂ sensors. The response increases gradually and can reach to 90 when the glycol concentration is 100 ppm, which is about 2 times higher than that of undoped SnO₂ sensor with calcinations and 3 times higher than that of the sensor without calcinations. It also indicates that the detection limit could be down to 5 ppm-level with a response about 5. Compared with the performance of the sensors to ethanol, as shown in Figure 7(b), glycol gas is more active than ethanol, which leads to a higher response than ethanol. To the best of our knowledge, only Zhang et al.⁷ fabricated porous SnO₂ nanotubes sensor to detect glycol while operating at 300°C. Compared with the above, the optimal operating temperature of our sensor is down to 240°C, reduced 60°C than that of porous SnO₂ nanotubes sensor. The further comparison between the sensing performances of our sensor and reported literature is summarized in Table 1.

The response-recovery behavior is also vital characteristic parameters for gas sensors. It was defined as the time needed for the sensor-resistance to change by 90% of the difference from the maximum after injecting and removing the detected gas. It can be clearly observed that the response of Zn-doped SnO₂ sensor increased abruptly after the injection of ethanol and decreased rapidly, then recovered to its initial value after the test gas was released. The response and recovery time are about 14 and 25 s (ethanol), as shown in Figure 8(a). However, when glycol was injected into the box, the response and recovery time was prolonged to 66 s and 97 s

(Figure 8(b)), which is much longer than that of ethanol in Figure 8(a). This may be attributed to the lower operating temperature (240°C) and higher boiling point of glycol (197.3°C).

Selective detection of the target gas remains a challenge for the application of metal oxide semiconductor based gas sensor⁵⁰. To identify the selectivity of the three sensors, the cross response properties of the sensors were examined by exposing the sensors to 100 ppm glycol and other gases like ethanol, acetone, benzene, para-xylene, water and hydrogen at 240°C, as summarized in Figure 9. It was seen that the response of Zn-doped SnO₂ sensor to 100 ppm glycol is much higher than that of other sensors. The response can reach to 80, which was about four times higher than the response of ethanol and more than eight times than that of other gases, indicating an excellent selectivity to glycol.

As a typical n-type metal oxide semiconductor, SnO₂ based sensor belongs to the surface-controlled type, and the most widely accepted model is the formation of a charge depletion layer in the near-surface region of each grain, relative to the interior parts, due to electron trapping on adsorbed oxygen species^{31,51}. The conductance of the n-type semiconductor is determined by the amount of electrons in its conduction band. Thus, according to a standard model⁵², when SnO₂ sensor is exposed to air, oxygen molecules will be adsorbed on its surface and further capture electrons from the conduction band to form oxygen ions (O₂⁻, O²⁻, O⁻). It will form a depletion region, resulting in the increase of the sensors resistance. When the sensors are exposed to a reducing gas such as glycol or ethanol, the oxygen negative ions will react with the target gas molecules and release the trapped electrons back to the conduction band of SnO₂, which reduce the amount of surface adsorbed oxygen species, and lead to an increase of the carrier concentrations of the sensors. Consequently, the depletion layer on the surface of the sensors becomes thin, which exhibit the decrease of sensor resistance^{7,53}. Based on the formula of response ($S = R_a/R_g$), the sensor shows a high response. Moreover, after the doped of Zn, the response of the sensors is enhanced

Table 1 | Sensing properties of Zn-doped SnO₂ hierarchical nanostructures and other reported gas sensors working under different operating temperatures

Sensing materials (preparation)	[ethanol/glycol](ppm)	R_a/R_g	$T_{sens}(^{\circ}C)$
SnO ₂ -ZnO thin film ⁴⁷	200 (ethanol)	4.69	300
Zn-doped SnO ₂ nanorods ³⁰	200 (ethanol)	17	270
ZnO-doped porous SnO ₂ nanospheres ⁴⁸	200 (ethanol)	20	150
SnO ₂ /ZnO hierarchical nanostructures ⁴⁹	100 (ethanol)	6.2	400
Porous SnO ₂ Nanotubes ⁷	200 (ethanol) 20 (glycol)	16.7 17.2	300
Our work	200 (ethanol) 100 (glycol)	33 90	320 240

Figure 8 | Response and recovery time of the S2 (Zn-doped SnO₂ 600°C) sensor to 100 ppm ethanol and glycol gas at the operating temperature of 320°C and 240°C, respectively.

obviously. The high response of Zn-doped SnO₂ observed here can be attributed to the following factors. Firstly, the grain size of SnO₂ will decrease with the doped of Zn. Due to the above mentioned, the surfaces of the SnO₂ nanosheets become more reactive and absorb more oxygen molecules to form ionized oxygen species^{32,54}. Secondly, the specific surface area of Zn-doped SnO₂ is increased. This means that the amount of oxygen can be absorbed and ionized on the surface of Zn-doped SnO₂. In addition, according to the solid state chemistry theory, the quantity of oxygen vacancies in Zn-doped SnO₂ nanostructures is also increased due to the substitution of Zn²⁺ for Sn⁴⁺. Thus, owing to the more oxygen species adsorbed on the surface of SnO₂ and more surface oxygen vacancies in the Zn-doped SnO₂ nanostructures, the Zn-doped SnO₂ sensor shows a higher response.

Figure 10(a) shows variations in adsorption spectra of MO organics dye solution in the presence of the Zn-doped SnO₂ (S2) photocatalyst irradiated by a UV lamp for different time. It indicates that the concentration of MO decreases as the irradiation time increasing by measuring the intensity of characteristic absorption peak (465 nm). Different degradation efficiencies for MO, S0, S1 and S2 can be observed directly in Figure 10(b). It can be seen obviously that S2 (Zn-doped SnO₂) exhibits more excellent photocatalytic activity

toward MO with the degradation efficiency of 92% than that of others (MO, 23%; S0, 55%; S1, 75%). Moreover, the photocatalytic performance is also much higher than those reported. For example, Yang et al.⁵⁵ synthesized ZnO-SnO₂ composite to degrade MO dye, and the degradation efficiency only reached to 60% in 100 min. Kowsari et al.⁵⁶ also fabricated ZnO/SnO₂ nanocomposites to degrade MO dye, and the degradation time was longer than 200 min. The higher degradation efficiency may be ascribed to the specific morphology of S2, which provides larger specific surface area than others, as shown in Figure 4. Compared with S0, the degradation efficiency of S1 was enhanced to 75% from 55% (S0), which indicates an increase of photocatalytic activity after the process of calcinations, leading to better crystallinity. Generally, the crystallinity of the photocatalysts plays a crucial role in the enhancement of the separation of the e⁻/h⁺ pairs.

In general, the specific surface area plays a main role during photocatalytic degradation of dye molecules. On the basis of the photocatalytic mechanism^{57–59}, it is known that the highly reactive ·OH and O₂⁻ are generated on the surface of photocatalysis under UV radiation¹. Therefore, the surface characteristic of nanoparticles will greatly influence its photocatalytic activity. On the basis of the above analysis, the Zn-doped SnO₂ catalyst showed the best photocatalytic activity, this result can be attributed to the special hierarchical structure, and better crystallinity.

Figure 9 | Selectivity of three sensors for different target gases with same concentration at 240°C.

Conclusion

In summary, a facile and simple method has been developed for preparing undoped and Zn-doped SnO₂ nanostructures. The as-prepared Zn-doped SnO₂ hierarchical architectures were consisted of interconnected ultrathin nanosheets. It was found that the Zn doping plays an important role in controlling the morphologies and structures of the products. The as-prepared nanostructures were used as the efficient gas sensing materials to detect a series of flammable and explosive gases, and photocatalysts for the degradation of methyl orange (MO) under UV irradiation. The Zn-doped SnO₂ gas sensor exhibits highly sensitive and selective sensing properties to glycol gas. The response can reach to 90 for 100 ppm glycol which is much higher than that of undoped SnO₂. The as-prepared Zn-doped SnO₂ hierarchical nanostructures were also used as efficient photocatalyst and exhibited excellent degradation for MO. The photocatalytic MO degradation rate of Zn-doped SnO₂ catalyst is much higher than that of undoped SnO₂ at the same UV irradiation time. This work demonstrates that the simply prepared Zn-doped SnO₂

Figure 10 | Variations in adsorption spectra of MO organic dye solution in the presence of the photocatalyst irradiated by a UV lamp for different time: (a) S2 (Zn-doped SnO₂ 600 °C), and (b) photocatalytic degradation of MO, S0, S1, S2.

nanostructures have a potential application in glycol gas sensor or MO photocatalytic degradation.

Acknowledgments

Thanks University of Jinan (UJN) for the support on new staff, and the project supported by the Taishan Scholar (No. TSHW20120210), the National Natural Science Foundation of China (Grant No. 11304120, 11174112, 61106059), the Encouragement Foundation for Excellent Middle-aged and Young Scientist of Shandong Province (Grant No. BS2012CL005).

Author contributions

Z.Q.Q. and J.D.X. designed the experiments. Z.Q.Q. performed the experiments. H.J.Z. and D.X.L. performed the SEM observations. C.B.Q. performed TEM observations. Z.Q.Q., J.D.X. and X.X.J. discussed and commented on the experiments and results, and wrote the paper.
