When a diatomic molecule is ionized by an intense laser field, the ionization rate depends very strongly on the inter-nuclear separation. That dependence exhibits a pronounced maximum at the inter-nuclear separation known as the “critical distance”. This phenomenon was first demonstrated theoretically in H_2^+ and became known as “charge-resonance enhanced ionization” (CREI, in reference to a proposed physical mechanism) or simply “enhanced ionization”(EI). All theoretical models of this phenomenon predict a double-peak structure in the R-dependent ionization rate of H_2^+ . However, such double-peak structure has never been observed experimentally. It was even suggested that it is impossible to observe due to fast motion of the nuclear wavepackets. Here we report a few-cycle pump-probe experiment which clearly resolves that elusive double-peak structure. In the experiment, an expanding H_2^+ ion produced by an intense pump pulse is probed by a much weaker probe pulse. The predicted double-peak structure is clearly seen in delay-dependent kinetic energy spectra of protons when pump and probe pulses are polarized parallel to each other. No structure is seen when the probe is polarized perpendicular to the pump.

The ionization of atoms and molecules by strong laser fields is fundamentally important for understanding laser-matter interactions in general. The ionization of molecules is generally much more complex than that of atoms, since ionization processes depend sensitively on nuclear coordinates, such as molecular alignment and inter-nuclear distances. It has been found, both experimentally^{1–6} and theoretically^{7–13} that the ionization rate of a diatomic molecular ion can be dramatically enhanced (by orders of magnitude) when its inter-nuclear separation reaches so-called critical distance. This phenomenon appears to be a universal feature of molecular ionization, and it was recently demonstrated in tri-¹⁴ and poly-atomic¹⁵ molecules.

The fundamental physical mechanism of EI is well understood for H_2^+ ^{9–11} (see Fig. 1(b)) and should operate similarly in other molecules with odd number of electrons. When H_2^+ with its double-well potential is exposed to a static electric field the electron localized in the upper potential well will experience potential barrier suppressed by the Coulomb field of the second proton and it can much more easily tunnel out than an atomic electron. However, for this to happen in an oscillating electric field of a laser pulse the electron first has to be localized in the upper potential well. Therefore, both electron and nuclear dynamics are playing a role in the interaction: the inter-nuclear distance needs to be large enough for substantial electron density to remain trapped in the upper potential well (if that distance

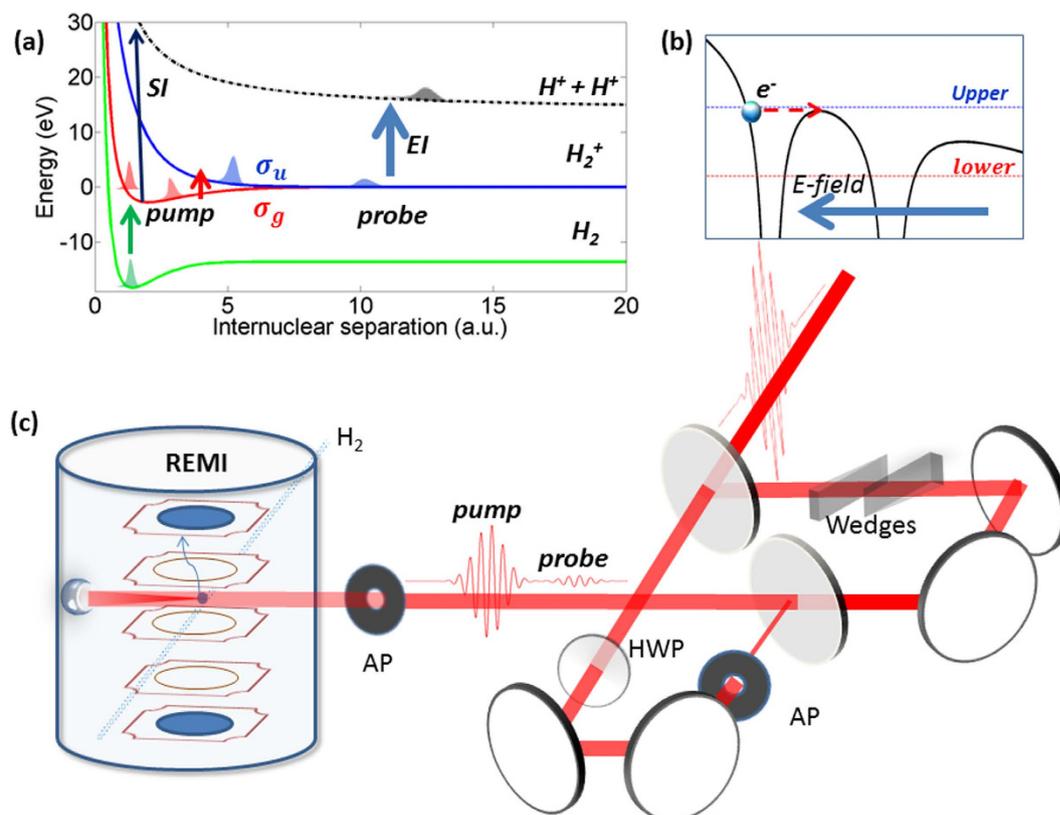

Figure 1. (a) Illustration of the enhanced ionization pathway when the hydrogen molecule interacts with an intense pump-probe laser field. Green arrow represents the tunnel ionisation of H_2 by the pump field, which launches a coherent Franck-Condon wavepacket from the ground state of H_2 (green line) onto the σ_g curve of H_2^+ (red line). At the tail of the pump pulse, this wavepacket may be further excited to σ_u curve of H_2^+ (blue line) by absorbing one photon from pump field (red arrow), producing a dissociating NWP. When the NWP reaches the critical region for enhanced ionization, the probe pulse projects (blue arrow) the NWP onto the Coulomb repulsive curve of H_2^{2+} . (b) Fundamental physical mechanism of EI. When H_2^+ with its double-well potential (black line) is exposed to a static electric field (blue arrow) the electron localized in the upper potential well will experience potential barrier suppressed by the Coulomb field of the second proton and it can much more easily tunnel out (red dashed arrow) than an atomic electron. (c) Experimental setup. REMI - reaction microscope; AP - adjustable aperture; HWP - half-wave plate.

is too small the internal barrier is too low and the electron can follow the field instantaneously) yet small enough for significant suppression of the internal barrier. While simple physical reasoning readily accounts for existence of a critical distance, quite curiously, all theoretical calculations of various degrees of sophistication predict not one but two adjacent maxima for ionization rate in the critical region of R . The origin of this double-peak structure remains obscure and its very existence until now had no experimental confirmation. Obviously, the very concept of R -dependent ionization rate is only meaningful in the context of the fixed-nuclei approximation. So naturally, failure to observe the double-peak structure predicted by the fixed-nuclei theoretical models was interpreted as a failure of the fixed-nuclei approximation itself for fast-moving and spatially-extended nuclear wavepackets in H_2^+ . Therefore, our observation of the predicted double-peak structure supports the validity of the fixed-nuclei approximation in this specific context.

To measure the R -dependent ionization rate in H_2^+ one must generate the target molecular ion with different (and well controlled) distributions of inter-nuclear separations. That could only be achieved in a pump-probe experiment, where the pump would ionize neutral hydrogen and generate nuclear dynamics in the resulting molecular ion, which could then be further ionized by a delayed probe pulse. Since this nuclear dynamics is very fast (it takes about 15 fs for the wavepacket to reach the outer turning point) both pulses have to be very short – no more than 2 cycles in duration at 800 nm wavelength (6 fs). Several such experiments have been performed^{4,5} and failed to register the double-peak structure. It has been suggested that the “wash-out” effect due to fast nuclear motion⁵, and the fast depletion of H_2^+ at the first peak¹⁶, make it hard, if not impossible, to observe the double-peak structure. The “wash-out” refers to both fast motion of the nuclear wavepacket (it takes only 8 fs for the centre of wavepacket to cover the distance between the two peaks) and fast spread of the wavepacket in radial direction as it propagates. We

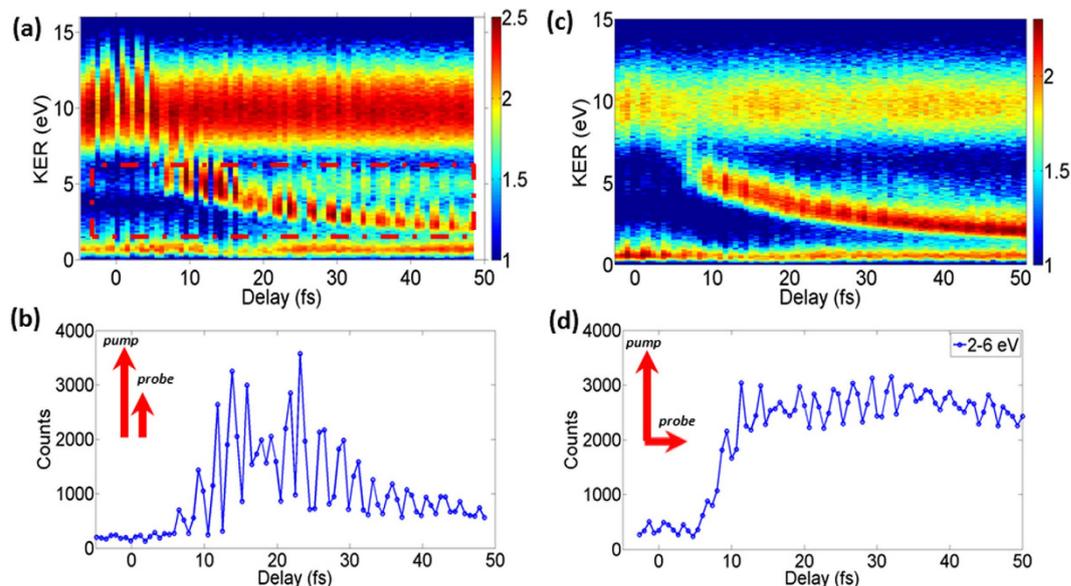

Figure 2. The measured delay-dependent KER spectra when pump and probe polarization axes are parallel (a) and perpendicular (c) to each other. The probe intensity for perpendicular polarization is approximately five times higher than for parallel one, as less intense pulses produced no significant EI signal in the cross-polarized configuration. Energy-integrated delay dependent ionization yields with parallel (b) and cross (d) polarized pump and probe. Note the double-peak structure for parallel polarization.

demonstrate that the “wash-out” effect can be overcome by using sufficiently short laser pulses. It should also be pointed out that all previous experiments were performed with pump and probe pulses having the same or very similar peak intensities, sufficiently high to ionize neutral hydrogen molecules with significant probability. However, it is predicted that H_2^+ at the critical distance is much easier to ionize than H_2 at its equilibrium R. For that reason, in order to observe the double-peak structure experimentally, not only the probe pulses have to be short in duration (as defined by full width at half-maximum of their intensity envelope) but also their instantaneous intensity may exceed the saturation intensity at the critical distance only for a very short time (less than 8 fs). Otherwise, the ionization will deplete the H_2^+ way before the peak intensity is reached, making the delay-dependent measurements meaningless. Keeping that in mind, we performed a pump-probe experiment using ultra-short (6 fs) pulses, with probe pulse being an order of magnitude less intense than the pump pulse (pump - $6 \times 10^{14} \text{ W/cm}^2$, probe - $6 \times 10^{13} \text{ W/cm}^2$). Under such conditions the “wash-out” effect as well as the fast depletion of H_2^+ by the probe could be suppressed and the predicted double-peak structure could be seen. Further details of our experimental setup are given in the Methods.

The process of ionization of H_2 by the pump-probe field is illustrated in Fig. 1(a). The final Coulomb explosion (CE) produces a pair of energetic protons, with kinetic energy release (KER) given by the instantaneous position of the NWP. That is, $\text{KER} = \frac{1}{R} + E_0$, where E_0 is the initial kinetic energy obtained in dissociation process³ and R is inter-nuclear separation at the moment of second ionization. By changing the time delay, we can control the inter-nuclear separation at which ionization of the molecular ion takes place.

The measured KER spectra together with energy-integrated yields for the EI channel as a function of delay are shown in Fig. 2. The channel with KER around 10 eV comes from the sequential double ionization of H_2 by the pump pulse, and the channel with low KER of $\sim 0.7 \text{ eV}$ comes from the bond softening dissociation of H_2^+ , followed by single ionization of the atomic H fragment. These channels are produced by the pump pulse alone and show no dependence on pump-probe delay. The channel with KER in the (2–6) eV range shows strong delay dependence and is attributed to ionization of H_2^+ by the probe pulse. The vanishing EI yield around zero delay proves that our laser pulse is sufficiently short and the pre- and post-pulses do not have enough intensity to induce enhanced ionization, so that the background signal of the EI yield produced by either pump or probe pulse alone is suppressed. The EI signal becomes visible when the delay is increased to about 7 fs. From then on, two branches in the time-dependent KER spectra develop. The stronger branch has a decreasing central KER with increasing delay that originates from the dissociating NWP produced by the pump pulse. The weaker branch has a delay independent KER centred at around 4.5 eV and it originates from the fraction of NWP remaining bound on the ground-state potential of molecular ion which is ionized almost exclusively at its outer turning point. The energy-integrated yield of the EI channel presents two clear peaks at delays around 15 fs and 23 fs reflecting the R-dependent ionization probability for the dissociating molecular ion (Fig. 2(b)).

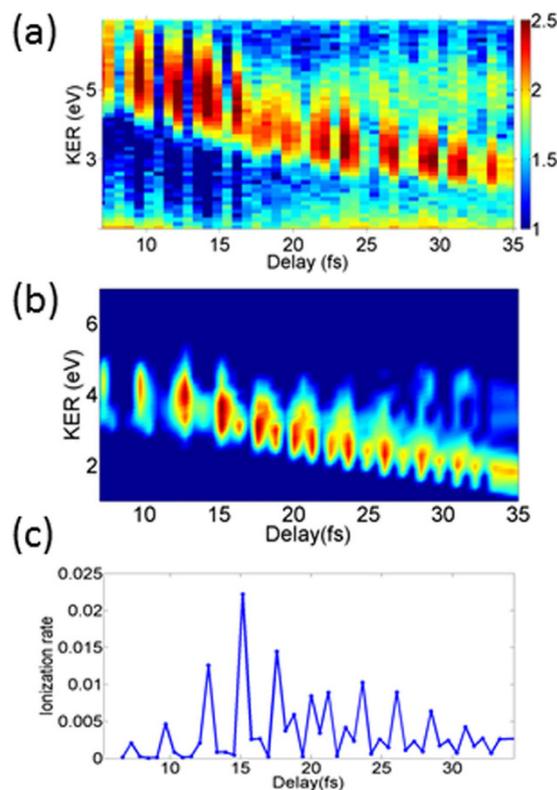

Figure 3. (a) Measured delay-dependent KER spectrum of the EI channel (same as in Fig. 2(a)) compared with the simulated delay-dependent KER spectrum (b). (c) The corresponding simulated delay-dependent energy-integrated ionization rate (see Methods for details). A periodic modulation of proton yield at a period of the driving laser (~ 2.5 fs) is also visible in the spectra. As confirmed by our numerical simulation, such modulation comes from the interference between the tail of the pump pulse and the probe pulse.

This time-dependent double-peak structure in the yield, in conjunction with the time-dependent KER identifying the channel, presents sufficient proof of the double-peak structure in R-dependent ionization probability. In order to relate the time delays to the inter-nuclear separations and to confirm our assignment we also performed a numerical simulation (see Methods for details). The results of that simulation are presented in Fig. 3. The simulated delay-dependent KER spectra for enhanced ionization channel have the same structure as observed in the experiment (Fig. 3(a)): a strong branch with delay dependent KER and a weak branch with delay-independent KER are present in the simulation as well. However, our model fails to quantitatively reproduce relative heights of the two peaks, most likely due to its reduced dimensionality with the electron motion constrained to the laser polarization direction. There are some theoretical indications that off-axis electron trajectories contribute significantly to the second peak¹¹, implying that a quantitative theoretical description will require a full-dimensional treatment of electrons. The periodic modulation of the yield with a period equal to the laser cycle (2.7 fs) seen in the experiment is due to interference of the probe pulse with the extended pedestal of the pump pulse. Including such pedestal in the modelled pump pulse (see Methods) faithfully reproduces this modulation. Since no enhanced ionization was observed due to the probe pulse alone, we can conclude that the actual pedestal of the pump pulse at relevant delays from its peak is much weaker than the probe pulse and aside from the laser-cycle modulation the pedestal does not affect the underlying physics and our conclusions.

It is known from theory and experiments that EI is very anisotropic, occurring only in molecules oriented within a narrow angle of laser polarization direction. Therefore, we would not expect to see any maximum in the time-dependent ionization yield for molecules aligned normally to laser polarization. To test this prediction we repeated our experiment, with the polarization axis of the probe pulse rotated by 90 degrees. The dissociating H_2^+ are preferentially created along the polarization direction of the pump pulse, because bond-softening which is responsible for most of the dissociation is strongly anisotropic. We could not observe any significant enhanced ionization for the same probe intensity we used for the parallel pump-probe polarization. We had to increase the probe intensity by a factor of five (to $3 \times 10^{14} \text{ W/cm}^2$) to see a comparable double-ionisation yield. The energy-integrated double-ionization yield increases monotonically with delay and remains constant after 15 fs while KER shows similar decrease with time as in the parallel-polarization case (see Fig. 2(c)). The yield dependence is explained purely by decrease in ionization potential in dissociating molecular ions. The EI mechanism

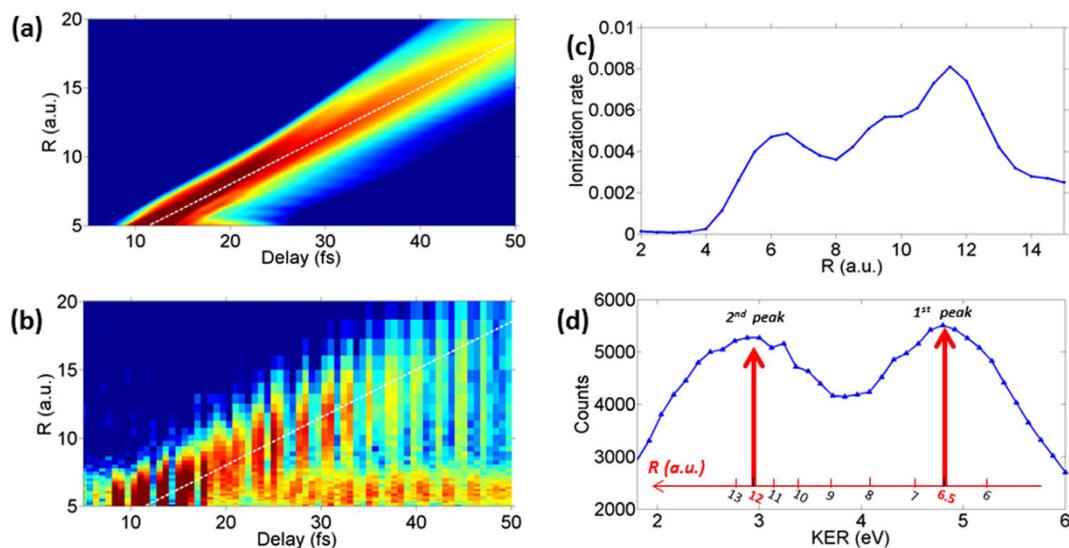

Figure 4. (a) Simulated time evolution of dissociating NWP density. The white dashed line represents the position of the NWP peak density as a function of delay. (b) Measured proton yield as a function of R and delay. The white dashed line is the same as shown in (a). (c) Simulated R -dependent ionization rate using fixed-nuclei model. (d) Measured KER spectrum integrated over all delays. The R axes in (b) and (d) are converted from KER by using $KER = \frac{1}{R} + 0.7 \text{ eV}$.

is not operational in perpendicular molecules. No peaks or double-peaks in ionization probability are expected and this is confirmed by our measurement.

The simulated dynamics of the dissociating NWP triggered by the pump pulse is shown in Fig. 4(a). We note that a dissociating NWP is propagating with a constant velocity of 0.35 a.u./fs, with slight spatial expansion. In Fig. 4(a), the time-dependent expectation value for the inter-nuclear distance $\langle R_0(\tau) \rangle$ is shown by the white dashed line. We also converted the experimental energy-dependent yield $Y(KER, \tau)$ into R -dependent yield $Y(R, \tau)$ using the relationship $KER = \frac{1}{R} + E_0$ where $E_0 = 0.7 \text{ eV}$ is the measured KER of the bond softening channel (Fig. 4(b)). The same dashed white line as in Fig. 4(a) is overlaid over the converted experimental spectra showing that the conversion truthfully reflects time evolution of NWPs. To extract the R -dependent ionization yield, we integrate the measured $Y(KER, \tau)$ over all delays. As shown in Fig. 4(d), a clear double peak structure is observed in the time-integrated KER spectrum, where the first peak is around 4.9 eV and the second peak is around 3 eV. By using the same conversion function of $KER = \frac{1}{R} + 0.7 \text{ eV}$, we can directly obtain inter-nuclear separations corresponding to the two peaks. The first peak is around 6.5 a.u., and the second peak is around 12 a.u., which agrees well with the fixed-nuclei model calculation (Fig. 4(b), see Methods for details of the simulation).

In conclusion, we have presented the first experimental confirmation of the existence of the double-peak structure in R -dependent ionization rate of H_2^+ , which has long been predicted by theory. We achieve this confirmation by performing a pump-probe experiment with a few-cycle probe pulse being 10 times weaker than the pump pulse. We determine that the ionization probability for H_2^+ is maximized at inter-nuclear separations of 6.5 a.u. and 12 a.u. in good agreement with theoretical predictions. Our numerical simulations agree well with the measurements and confirm our interpretation. Our results also confirm the validity and usefulness of the fixed-nuclei approximation for understanding ultrafast molecular dynamics. The well-resolved double peak structure also suggests that high degree of precision and control could be achieved in experiments on light diatomic molecules, opening new avenues in exploration of a variety of ultrafast processes and phenomena.

Methods

Experimental scheme. The schematic diagram of our experiment is shown in Fig. 1(c). A linear-polarized 6 fs 750 nm pulse is divided into a strong pump pulse and a weak probe pulse by a Mach-Zehnder interferometer, where the power of both pulses is individually controlled by apertures. The intensity of pump pulse ($6(\pm 2) \times 10^{14} \text{ W/cm}^2$) and probe pulse ($6(\pm 2) \times 10^{13} \text{ W/cm}^2$) at the laser focus is calibrated by making *in situ* measurements of the momentum of Ne^+ ions produced by circularly polarized pulses¹⁷. Our previous experiment^{18,19} has shown that such laser parameters of the pump pulse can support strong radiative coupling between σ_g and σ_u states of H_2^+ , which is essential for EI. The delay between pump and probe pulse is scanned from -5 fs to 50 fs with a step of 0.67 fs. The pulses were tightly focused by a silver-coated concave mirror ($f = 75 \text{ mm}$) installed inside a reaction microscope (REMI), onto a supersonic gas jet of hydrogen molecules. The polarization axis of the pump pulse is set to be parallel to the

time-of-flight axis of REMI, and a half-wave plate is used to control the polarization of the probe pulse to be either parallel or perpendicular to polarization of the pump pulse. All the ions were detected by a time- and position-sensitive detector (RoentDek), and the three-dimensional momentum vectors were determined. We used a momentum conservation coincidence filter to select proton pairs from the same hydrogen molecule.

Numerical simulation. We numerically solved the time-dependent Schrödinger equation (atomic units are used throughout unless indicated otherwise)²⁰

$$i\frac{\partial}{\partial t}\Psi(z, R; t) = \left[\frac{p_R^2}{2\mu} + \frac{1}{2}(p_z + A(t))^2 + V(z, R) + \frac{1}{R} \right] \Psi(z, R; t) \quad (1)$$

where μ is the reduced nuclear mass, p_R and p_z are nuclei and electronic momentum operators, $A(t)$ is the laser vector potential, and $A(t) = -\int_0^t dt' E(t')$. The form of the electric field $E(t)$ will be presented later. To reproduce the molecular potential energy curves in such a reduced dimensionality model, we wrote the Coulomb potential in the form²¹:

$$V(z, R) = -\sum_{s=\pm 1} \frac{1}{1/\alpha(R) - \alpha(R)/5 + \sqrt{(z + sR/2)^2 + (\alpha(R)/5)^2}} \quad (2)$$

where $\alpha(R)$ is the R-dependent soft-core-function. The simulation box extends from -3000 to 3000 a.u. along z dimension and from 0 to 40 a.u. along R dimension, and the spatial and time steps are $\Delta z = 0.3$ a. u., $\Delta R = 0.02$ a. u., $\Delta t = 0.2$ a. u. At the end of propagation $t = t_f$, we smoothly filtered out the wave function within the radius $\sqrt{R^2 + z^2} = 60$ a.u. and Fourier transformed the remaining part into the momentum representation $\tilde{\Psi}(p_R, z; t_f)$. The proton energy spectrum is $W(E) \propto |\tilde{\Psi}(p_R, z; t_f)|^2 / p_R$. We have checked that the simulation box is big enough that no wavepacket reached its boundaries during simulations, and the nuclear momentum and ionization probabilities converged.

We assumed that the single ionization of H_2 induced by the pump pulse could be described by the Franck-Condon approximation. Hence, we launched the coherent superposition of first ten lowest molecular vibrational states of H_2^+ , weighted by the Franck-Condon factors in the middle of the pump pulse. We obtained these ten states by propagating the wave function in imaginary time. One may note that the Franck-Condon approximation overestimates the population of higher vibrational states. Considering the R-dependent ionization potential, H_2 ionization tends to populate lower vibrational states of H_2^+ due to smaller ionization potential. We repeated the simulation with populations of the ten lowest vibrational states given by R-dependent ADK rate estimated for the pump laser intensity of about 4×10^{14} W/cm². Our simulation results show that both Franck-Condon and ADK approximation of the nuclear wavepacket agree well with experimental observations.

The coherent nuclear wave packet moves to the outer turning point, and is dissociated by the tail of the pump pulse or the pedestal, followed by the ionization triggered by the time-delayed probe pulse. According to the experimental conditions, the pump pulse generally sits on the pedestal with long duration but a much lower intensity. In the simulations, we used the combined laser fields as following:

$$E = E_{pedestal} \sin(\omega t) + E_{probe} \sin[\omega(t - \Delta t)] f_{probe} \quad (3)$$

where $f_{probe} = \cos^2[\pi(t - \Delta t)/(5T)]$, $-2.5T < t - \Delta t < 2.5T$, T is the optical period, and $E_{pedestal} = 0.01$ a. u. (3×10^{12} W/cm²), $E_{probe} = 0.0413$ a. u. (6×10^{13} W/cm²).

Fixed-nuclei model simulation. We numerically solved the time-dependent Schrödinger equation in cylindrical coordinates by taking the inter-nuclear distance R as a parameter,

$$i\frac{\partial}{\partial t}\Psi(\rho, z; t) = \left[\frac{p_\rho^2}{2} + \frac{1}{2}(p_z + A(t))^2 - \sum_{s=\pm 1} \frac{1}{\sqrt{(z + sR/2)^2 + \rho^2}} \right] \Psi(\rho, z; t) \quad (4)$$

The laser field is identical to the probe pulse described in Experimental scheme and the simulation algorithms are same as before. The simulation box is big enough that no wave packet reaches the numerical boundaries. We keep propagating the nuclear wave packet after the laser field is finished until all observations are converged. The ionization probability is counted by integrating the probability distributed in the area $\sqrt{\rho^2 + z^2} > 60$ a.u. at the end of the propagation. Compared to the moving nuclei simulation, here the description for the electron is complete considering the rotational symmetry.
