Marc Monot¹, Catherine Eckert^{3,4}, Astrid Lemire^{3,4}, Audrey Hamiot¹, Thomas Dubois¹, Carine Tessier^{3,4}, Bruno Dumoulaud⁵, Benjamin Hamel⁶, Amandine Petit^{3,4}, Valérie Lalande^{3,4}, Laurence Ma², Christiane Bouchier², Frédéric Barbut^{3,4,*} & Bruno Dupuy^{1,*}

The major virulence factors of *Clostridium difficile* are toxins A and B. These toxins are encoded by *tcdA* and *tcdB* genes, which form a pathogenicity locus (PaLoc) together with three additional genes that have been implicated in regulation (*tcdR* and *tcdC*) and secretion (*tcdE*). To date, the PaLoc has always been found in the same location and is replaced in non-toxigenic strains by a highly conserved 75/115 bp non-coding region. Here, we show new types of *C. difficile* pathogenicity loci through the genome analysis of three atypical clinical strains and describe for the first time a variant strain producing only toxin A (A⁺B⁻). Importantly, we found that the PaLoc integration sites of these three strains are located in the genome far from the usual single known PaLoc integration site. These findings allowed us to propose a new model of PaLoc evolution in which two “Mono-Toxin PaLoc” sites are merged to generate a single “Bi-Toxin PaLoc”.

The Gram-positive spore-forming bacterium *Clostridium difficile* is the major etiological agent of intestinal diseases associated with antibiotic therapy, with clinical manifestations that range from diarrhoea to pseudomembranous colitis and possible death¹. The incidence and severity of *C. difficile* infection (CDI) have significantly increased over the past fifteen years, mainly due to the emergence of new strain variants, such as hypervirulent PCR-ribotype 027 strains¹. Therefore, CDI has a considerable impact on healthcare systems in North American and European hospitals². Moreover, 23% of *C. difficile* infections are potentially undiagnosed due to the absence of clinical suspicion and suboptimum laboratory diagnostic methods³.

The major virulence factors of *C. difficile*, toxin A (TcdA) and toxin B (TcdB), are two members of the Large Clostridial Toxin (LCT) family, which are potent monoglycosyltransferases that disrupt the gut epithelium. Genes encoding TcdA (*tcdA*) and TcdB (*tcdB*) are located within the pathogenicity locus (PaLoc), a 19.6 kb chromosomal region that also contains three additional genes (*tcdR*, *tcdE* and *tcdC*). *tcdR* encodes an RNA polymerase sigma factor that positively regulates toxin expression⁴, *tcdE* encodes a bacteriophage holin required for toxin secretion⁵, and *tcdC* encodes a negative regulator of TcdR⁶. The PaLoc is always found in the same genomic location and is replaced in the non-toxigenic strains by a highly conserved 115/75 bp non-coding region^{7,8}. A third unrelated binary toxin (CDT) is found in 23% of *C. difficile* strains, but its role in disease remains unclear⁹. This toxin is encoded in a separate region of the chromosome (CdtLoc) containing genes for both components of CDT (*cdtA* and *cdtB*) and a regulatory gene (*cdtR*)¹⁰.

The genetic polymorphisms of the PaLoc have been confined to a toxinotyping scheme, a PCR-RFLP-based method that was developed by Rupnik and colleagues¹¹ that groups strains with identical changes in the PaLoc when compared to the other strains. In both Gram-negative and Gram-positive bacteria, many genes encoding virulence factors, including toxins, are located within mobile genetic elements, such as pathogenicity islands (PAIs). Unlike the PaLoc, PAIs contain direct repeats and insertion sequences, which are responsible for high-frequency deletions, duplications or amplifications, leading to a high level of variation and evolutionary diversities for virulence-factor-encoding genes. Even if *C. difficile* PaLoc does not fit the generally accepted definition of a PAI¹², horizontal toxin gene transfer and PaLoc recombination events are the main mechanisms of toxin diversity¹³.

Comparative phylogenomics of well-characterised isolates of *C. difficile* revealed that the *C. difficile* population structure is divided into six distinct phylogenetic clades (Clades 1, 2, 3, 4, 5 and C-1)^{8,14}. With the exception of Clade C-1, most of these clades include toxinogenic strains (A⁺B⁺ or A⁻B⁺)⁸, which are mainly found in Clade 1 and to a lesser extent in Clades 2 and 3. Recently, toxinogenic strains were discovered in Clade 5^{15,16}. The number of toxinogenic genotypes that have been identified across each clade varies widely⁸, which might be consistent with independent PaLoc acquisition followed by clonal expansion. Thus, the relationship between PaLoc types and *C. difficile* strains is likely in constant evolution, and recent PaLoc acquisitions and exchanges likely play an important role in the under-diagnosis of CDI.

In this work, we show a new type of genomic organisation of the *C. difficile* PaLoc through the analysis of three atypical strains isolated from CDI. We describe for the first time a variant strain producing only TcdA (A⁺B⁻) and new toxigenic strains (A⁻B⁺CDT⁺) strains that belong to Clade C-I. For the latter, we found that both PaLoc and CdtLoc are located in the same genomic region. Importantly, the PaLoc can be located at different sites of the genome, distant from the single, yet known, PaLoc integration site, thereby opening new questions regarding PaLoc evolution. Based on the sequence analysis of these new PaLoc variants, we discuss a model merging two “Mono-Toxin PaLoc” to generate a single “Bi-Toxin PaLoc”.

Materials & Methods

Bacterial strain identification. The RA09-070 strain was isolated during a French national prospective and multicentric study of CDI¹⁷, and the SA10-050 and CD10-165 strains were sent to the National Reference Laboratory for *C. difficile* for characterisation (Paris, France). The identification of the three strains as *C. difficile* was confirmed using Matrix-assisted laser desorption ionisation (MALDI) time-of-flight (ToF) mass spectrometry (Bruker) and the glutamate dehydrogenase (GDH) component of the *C. diff* Quik Chek Complete assay (Alere, Jouy-en-Josas, France). DNA was extracted with the InstaGene Matrix kit (Bio-Rad Laboratories, Hercules, California, USA). The entire PaLoc was explored by the amplification of fragments of both *tcdA* (A1, A2 and A3) and *tcdB* (B1, B2 and B3) as described in the toxinotyping schema that was developed by Rupnik *et al.*¹¹. PCR amplifications of the *tcdC*, *cdtA* and *cdtB* genes were performed using primers described elsewhere^{11,17}. PCR-ribotyping was performed as recommended by Bidet *et al.* and capillary-gel based electrophoresis patterns were compared to a collection of 26 well-defined ribotypes (001, 002, 003, 005, 012, 014/020/077, 015, 017, 018, 019, 023, 027, 029, 046, 050, 053, 056, 070, 075, 078, 126, 081, 087, 106, 117 and 131)¹⁸. The strains were characterised by MLST and ST types were identified using two MLST schemes that were developed by Lemee *et al.*¹⁹ and by Griffiths *et al.*²⁰.

In vitro toxin B production was tested by the cytotoxicity assay on MRC-5 cell monolayer as described elsewhere²¹. Toxin detection was also tested by the *C. diff* Quik Chek Complete assay (Alere, Jouy-en-Josas, France) and Vidas *C. difficile* Toxin A and B (Biomérieux, Marcy l’Etoile, France), performed directly on colonies. Molecular methods, such as *illumigene C. difficile* (Meridian Bioscience, OH, USA), Xpert *C. difficile* (Cepheid, CA, USA), Rida Gene *C. difficile* and Toxin A/B (R-biopharm, Darmstadt, Germany), were performed from colonies, as recommended by the manufacturers.

DNA sequencing and genome assembly. DNA was extracted from overnight culture growth in TY media, inoculated from one colony as previously described²². Single-end multiplex libraries were created, and the sequencing was performed using the Illumina HiSeq 2000 platform. The read length was 110 bp, and isolates were sequenced at least to an average coverage of 100-fold (20, 5 and 6 billion reads, respectively, for RA09-70, SA10-050 and CD10-165). Sequencing reads were first scanned to remove the adaptor sequences and were then assembled *de novo* into contigs using Velvet²³. Thereafter, contigs were reorganised using Blast alignment against the genome sequence of the reference *C. difficile* 630 strain. All of the contigs that did not match the sequence of the reference strain were localised at the end of the contigs that were assembled to obtain a whole genome scaffold for each of the isolates. Finally, the Microscope work flow²⁴ was used for an automatic functional annotation of each CDS.

The sequenced reads of the *C. difficile* RA09-70, SA10-050 and CD10-165 strains were deposited in the Sequence Read Archive (Accession Numbers PRJNA255280, PRJNA260039 and PRJNA260040) and their annotated genome in the DDBJ/EMBL/GenBank databases (GenBank Accession Numbers JPPA00000000, JRHM00000000 and JRHN00000000).

Phylogenetic Analyses. Strains representative of the diversity of *C. difficile* PCR-ribotypes and of the six clades (1, 2, 3, 4, 5 and C-1) were chosen (Table S1). The maximum likelihood trees with 500 bootstrap replicates were constructed by performing a phylogenetic analysis of the *cdul* and *ccd3* (Fig. S3) genes and of the TcdA and TcdB proteins (Fig. S8 and Fig. S9) using MEGA 6.0²⁵.

Analysis of the *tcdR* regulatory region. We performed an *in silico* analysis of the regulators (CodY and CcpA) and sigma factors (TcdR and SigD) binding sites that were present in the *tcdR* promoter regions of strains CD630, CD10-165/SA10-050 and RA09-70. For this analysis, we scanned the 400 bp intergenic region upstream of *tcdR* gene with the published consensus binding sites of CodY “AATTTTCWGAAAATT”²⁶, CcpA “RRGAAAANGTTTCWW”²⁷ and the -35 box of the TcdR promoter “TTTACA”²⁸ and the SigD promoter “TAAAN(13–19)CGW”²⁹. We adjusted the number of mismatches in each consensus to recover the experimentally verified *tcdR* binding sites of CD630 for CodY (three known sites recovered with four mismatches), CcpA (2 known sites recovered with three mismatches), TcdR (2 known sites recovered with 0 mismatches) and SigD (1 known site recovered with 0 mismatches) (Fig. S6).

UviB holin activity assay. The pBRQ(Δ RBS), a derivative of the pJN4³⁰ deleted in the S λ gene ribosomal binding site (RBS), was used to create constructs in which the UviB gene was placed under the control of the λ pR' promoter (late transcription regulatory (LTR) region, spanning from the 3' end of the antiterminator Q gene to the first base pair of the S holin gene)³⁰. The *uviB* gene coding sequence, including its own ribosomal binding site, was PCR amplified, digested and ligated to pBRQ(Δ RBS). To test the holin activity of UviB, lysogens of *Escherichia coli* strain MC1061 for a defective λ prophage bearing a nonsense mutation in its holin gene (λ Ci₈₅₇Sam7) or carrying a deletion in holin and endolysin genes [λ CmrD(SR)] were used as hosts for the plasmid constructs⁵, including plasmids pJN5 and pRG32, which carry the genes encoding the λ holin S¹⁰⁵ and TcdE, respectively⁵. Both λ (Sam7) and λ Cmr Δ (SR) encode a thermo-sensitive CI repressor (cI857) and are induced upon shifting the culture temperature from 30 °C to 37 °C³¹. Resultant strains were grown in LB broth at 30 °C until the OD600 reached 0.15–0.25 before the thermo-induction of the λ prophage at 42 °C for 15 min. Bacterial growth and lysis at 37 °C were then followed by monitoring the absorbance at 600 nm at 15 min intervals.

Results

Microbiological and molecular analysis of new variant *C. difficile* strains. The three strains that were investigated in this study were isolated from clinical samples. The RA09-070 strain was isolated from a 60-year-old man with antibiotic-associated diarrhoea, which was successfully treated by oral metronidazole without further recurrence. The SA10-050 strain was isolated from an 84-year-old man who presented febrile diarrhoea during the course of treatment for multiple myeloma. CDI was successfully treated by oral metronidazole. Finally, the CD10-165 strain was isolated from a 74-year-old man who presented abundant diarrhoea and severe pseudomembranous colitis. The patient deceased in the context of multiple organ failure and shock, and the death was directly attributed to *C. difficile*. The complete case report of these strains is described in the supplementary data.

Surprisingly, the immuno-enzymatic tests, the cytotoxicity assay and molecular tests that were used for the diagnosis of these *C. difficile* strains displayed insufficient results. Toxin detection of the RA09-070 strain was positive with the Vidas and with the *C. diff* Quik Chek Complete immunoassays (weak band) (Table 1A). However, this result was negative using the MRC-5 cell cytotoxicity assay, which detects TcdB only, suggesting that the RA09-070 strain produced TcdA but not TcdB. This result was consistent with the detection of TcdA by a dot blot experiment performed from the crude extract of the strain (Fig. S1). This result was partially confirmed by commercially available molecular diagnostic tests. Indeed, the detection of toxin genes was negative when using Xpert *C. difficile* (a diagnostic assay that targets only *tcdB*) and positive when using the Rida Gene *Clostridium difficile* Toxin A/B (a PCR-based method simultaneously detecting *tcdA* and *tcdB*) but was unexpectedly negative with *illumigene C. difficile*, which targets a highly conserved region of *tcdA* (Table 1A).

The toxin detection assay of the SA10-050 and CD10-165 strains also presented insufficient results: detection was negative with the Vidas immunoassay but positive with *C. diff* Quik Chek Complete and the MRC-5 cell cytotoxicity assay (Table 1A), suggesting that both strains produced only TcdB. Consistently, we were not able to detect TcdA from the crude extracts of both strains (Fig. S1). This result was also partially confirmed by molecular analysis. As expected, the detection of toxin genes of both strains was negative using *illumigene C. difficile* and positive with Xpert *C. difficile* (Table 1A). However, toxin gene detection was surprisingly negative with the Rida Gene *Clostridium difficile* Toxin A/B.

In addition, we showed all of the strains were negative for binary toxin, whatever the method used (Xpert *C. difficile* or home-made PCR) and for the PCR amplification of the *tcdC* gene (Table 1A).

The results of the toxinotyping of the three strains were also unexpected. PCR for B1, B2, B3 and A3 were negative for the RA09-070 strain, whereas PCR fragments A1 and A2 of the *tcdA* gene were positive. For the SA10-050 and CD10-165 strains, all three PCRs covering *tcdA* (fragments A1, A2, A3) were negative, and only the B1 and B2 fragments covering the *tcdB* gene were positive. These results suggest that these strains belong to new toxinotypes.

Table 1. Analysis of RA09-70, SA10-050 and CD10-165 strains. (A) Detection of toxin gene and toxin production by different molecular methods and immuno assays. (B) MLST analysis according to the schemes of Lemee *et al.*¹⁹ and Griffiths *et al.*²⁰. *weak band; GDH: glutamate dehydrogenase.

The PCR-ribotype profiles of the strains (Fig. S1) were unusual, *i.e.*, they did not match any of the most frequent PCR ribotypes¹⁷. Moreover, *in silico* MLST analysis (Table 1B) showed that the RA09-70 strain was close to strains that belong to the sequence type ST63, as reported by Lemee *et al.*¹⁹, and to ST200, as reported by Griffiths *et al.*²⁰. The SA10-050 and CD10-165 strains did not correspond to any sequence type that was reported by Lemée *et al.* but are respectively close to strains belonging to the ST206 and ST181 types that were reported by Griffiths *et al.* (Table 1B). By generating maximum likelihood trees from the *cdt1* and *cdd3* genes of at least three *C. difficile* strains per clade (Fig. 1 and Fig. S3), we showed that SA10-050 and CD10-165 belongs to Clade C-I. RA09-70 is a member of Clade 5 based on *cdt1* tree (Fig. 1) but apparently belongs to a distinct group according to the *cdd3* tree (Fig. S3). More strains as RA09-70 are needed to confirm its Clade.

In conclusion, we have characterised three clinical strains of *C. difficile* belonging to new toxinotypes displaying very specific and atypical features: the RA09-70 strain is the first description of a variant strain harbouring only the toxin-A-encoding gene. The SA10-050 and CD10-165 strains form, along with the

Figure 1. Phylogenetic relationship of the *cdw1* genes. Maximum likelihood tree reflecting the similarity of *cdw1* gene from representative clade *C. difficile* strains.

recently described strains of toxinotypes XXX and XXXI^{16,32,33}, a new group of A⁻B⁺CDT⁺ variants lacking a complete *tcdA* gene.

Atypical Genetic Organisation of the RA09-70, SA10-050 and CD10-165 PaLoc. To resolve the discrepancies between the toxin assay and the results of the molecular diagnostic analysis, we performed a whole-genome-sequencing approach for each strain to evaluate changes in the PaLoc genes that could explain the absence of toxin gene detection by some of the molecular *C. difficile* tests¹⁶. A *de novo* genome assembly showed that the PaLoc of RA09-70 strain is restricted to *tcdR* and *tcdA* genes (Fig. 2A). To ensure that the *tcdB*, *tcdE* and *tcdC* genes were really absent rather than lost in the assembly process, a deep search in the raw-data sequences was performed. By mapping all of the sequence reads onto the classic PaLoc sequence of the CD630 strain (Fig. 2B), we did not detect sequences from the raw-data file hybridising with the classic PaLoc sequence and thereby confirmed that *tcdB*, *tcdE* and *tcdC* genes were not present in strain RA09-70, not even in truncated form. However, we identified a new, putative CDS of 216bp between the *tcdR* and *tcdA* genes. This CDS encodes a protein of 71 amino acids containing a complete domain (IPR024405) related to the prophage protein BhlA/UviB, which are potentially involved in endolysin and bacteriocin secretion, respectively^{34,35}.

In the SA10-050 and CD10-165 strains, *tcdR*, *tcdB* and *tcdE* were the only genes present within the PaLoc (Fig. 2A). Using the aforementioned mapping method (Fig. 2B), we confirmed that *tcdA* and *tcdC* were completely absent. Interestingly, next to *tcdE*, we found a gene encoding an endolysin protein (CwlH) with N-acetylmuramoyl-L-alanine amidase activity, which supports the phage origin of the PaLoc and is consistent with the holin activity of TcdE⁵. Indeed, bacteriophage holins form holes in the host cell membrane to allow prophage-endolysin to cross the membrane and degrade bacterial peptidoglycan, resulting in cell lysis and the release of phage particles³⁶.

In addition, to clarify the structure of the PaLoc of these three strains, whole genome sequencing confirmed the integrity of the *tcdA* gene for the RA09-070 strain and the *tcdB* gene for the SA10-050 and CD10-165 strains. Moreover, the complete genome sequencing of the three strains revealed an unusual amino acid sequence variability of *tcdA* and *tcdB* (83% and 89% identity, respectively) compared to strain CD630 (Fig. S8 and Fig. S9). The weak homology between the sequences of toxin genes and the primers that were used for the A3 and B3 PCR fragments could explain the absence of PCR fragment amplification during toxinotyping as well as the detection of toxin genes with *illumigene C. difficile* and Rida Gene *Clostridium difficile* Toxin A/B tests, although the genomic targets of these assays are not

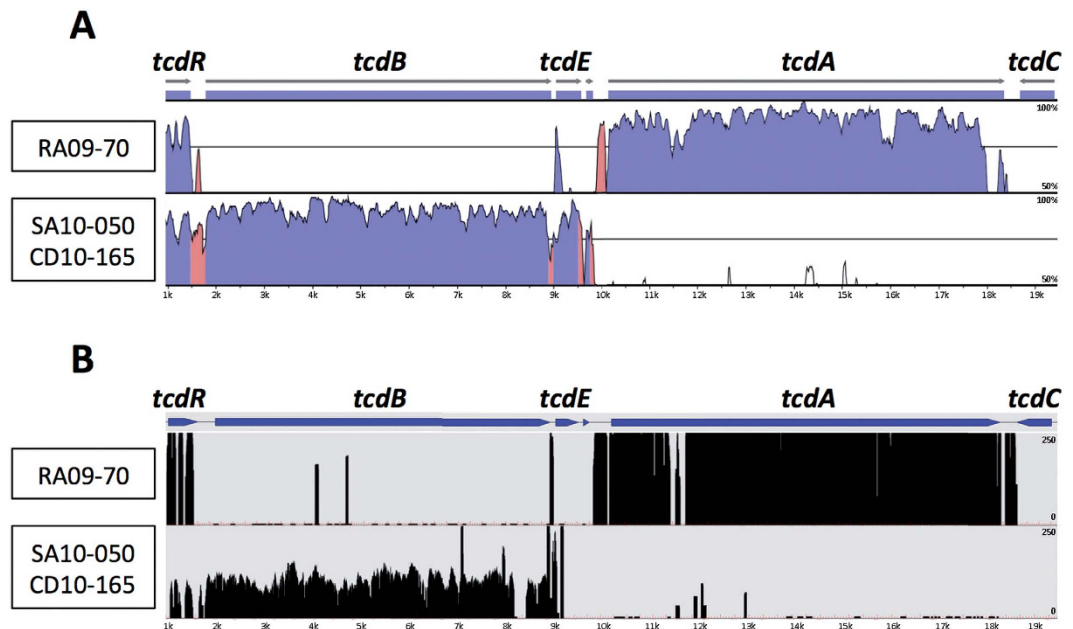

Figure 2. Genetic organization of the RA09-70 and SA10-050/CD10-165 PaLoc. (A) PaLoc of the 3 clinical strains were aligned with the CD630 PaLoc using LAGAN⁴⁸ (<http://lagan.stanford.edu>) and visualized by VISTA⁴⁹. The X-axis represents the CD630 PaLoc and the Y-axis the percent identity (from 50 to 100%) of the compared strain PaLoc by windows of 100 bp. The pink regions correspond to conserved non-coding sequences and the dark blue regions to CDS. (B) Mapping of the sequencing reads on the CD630 PaLoc. Alignment of sequencing reads onto the CD630 PaLoc was made using Blast⁵⁰ and visualized using COV2HTML⁵¹. The X-axis represent the CD630 PaLoc and the Y-axis the mapping coverage of the sequence reads (from 0 to 250).

publicly reported (Table 1A). Finally, the negative results that were obtained with the immunoassays may also be due to changes in the amino acid sequence of the toxins, thereby preventing recognition by the monoclonal antibodies that are used in the commercially available assays.

Interestingly, the whole genome sequencing approach identified a complete *cdt* locus in both the SA10-050 and CD10-165 strains that was not detected by molecular methods (Table 1A). This result seems to be due to the absence of sequence homology between the binary toxin genes of the SA10-050 and CD10-165 strains and the primers that were used for their amplification¹¹ (Table 1A).

PaLoc localisation of the RA09-70, SA10-050 and CD10-165 strains. Despite thousands of sequenced *C. difficile* strains from transmission or evolutionary studies^{8,37,38}, the *C. difficile* PaLoc was always found in the same genomic position that was replaced in non-toxinogenic strains by a highly conserved 115/75 bp non-coding region^{7,8}. However, the recent description of a new toxinotype strain¹⁶ suggested that PaLoc may also be inserted at other genomic sites, although the authors could not indicate the exact position and boundaries regions of the corresponding PaLoc¹⁶. Interestingly, in the three atypical strains, the usual classical PaLoc integration site contained the 75 bp PaLoc-replacing sequence and five genes that were previously described in non-toxicogenic strains of Clade 5 (for the RA09-70 strain) and Clade C-I (for the SA10-050 and CD10-165 strains)⁸, whereas the alternative PaLoc was present elsewhere in the genome.

According to whole-genome data, the RA09-70 PaLoc size (10.5kb) is smaller than the usual PaLoc size (19.6kb) of most of toxinogenic strains. Surprisingly, we found that genes flanking the PaLoc of the RA09-70 strain have no similarity with the *cdul* and *cdd1* genes upstream and downstream, respectively, of the classical studied PaLoc integration site to date⁸. However, these genes have more than 99% sequence identity with CD630_07750 and CD630_07760 genes (Fig. 3). Our analysis shows that both genes are conserved in RA09-70 and that 51 bases of the intergenic region were lost compared to the same region in the CD630 strain. We noted that there is no homology between this 51 base replacement sequence in the RA09-70 strain and the 115/75 bases of the classical PaLoc insertion sequence (Fig. 4b). As mentioned above, the PaLoc of the SA10-050 and CD10-165 strains is also inserted at a different genomic location, although it is more difficult to precisely identify the PaLoc insertion site. Indeed the PaLoc boundary regions in strains SA10-050 and CD10-165 are not conserved in any other available genome of *C. difficile*. Therefore, we assembled *de novo* the raw data reads into scaffold genomes from five Clade C-I strains that were described in Dingle *et al.*⁸ (Table S1). From the genome analysis of the RPH97 strain, we found the boundary regions of the CdtLoc-PaLoc region of the SA10-050 and

Figure 3. Localization of the RA09-70 PaLoc insertion site. The RA09-70 PaLoc is inserted between CD630_07750 and CD630_07760 genes of CD630. The RA09-70 PaLoc size is 10 556 bases and the 51 bases of the intergenic region lost in the RA09-70 strain are boxed in green. The syntheny was done using MaGe in the Microscope platform²⁴, CDS considered in syntheny are purple.

Figure 4. PaLoc organization of the RA09-70 and SA10-050/CD10-165 strains. Schematic description of the single PaLoc insertion site between non-toxicogenic (N-Tox) and toxicogenic (Tox) isolates representing Clade 1 (A), 5 (B) and C-I (C). PaLoc insertion site of the RA09-70 and SA10-050/CD10-165 strains correspond respectively to the Clade 5 and C-I. Colored boxes represent PaLoc replacing sequences (red: 115/75 bp, green: 51 bp) and the five genes (orf1-5) identified in this location in Clade 5 and C-I⁸ are represented by orange arrows. Strain ES130, described by Elliot and Coll.¹⁵ belongs to Clade 5.

CD10-165 strains and precisely determined the integration position (Fig. 4c) with a replacement of 449 bases compared to the RPH97 strain. This C-I replacement sequence has no homology with that of Clades 1 and 5.

In addition, the PaLoc of both strains is present next to the complete *cdt* locus (Fig. 4c), which has never been described before. The atypical genomic location of the RA09-70 PaLoc compared to the CD630 PaLoc and the organisation of PaLoc—CdtLoc of both SA10-050 and CD10-165 strains were confirmed by PCR experiments using internal and flanking PCR primers (Fig. S2).

Table 2. Amino acid identity of TcdR and CdtR among *C. difficile* strains. *Detailed in Supplementary Data Table S1.

To our knowledge, this is the first study clearly demonstrating that the PaLoc of *C. difficile* can be inserted at different genomic locations distant from the usual, unique PaLoc integration site that has been considered to date.

Sequence diversity of the RA09-70, SA10-050 and CD10-165 PaLoc and CdtLoc. As previously mentioned, *C. difficile* strains are distributed as variant toxinotypes based on the changes in their PaLoc, and to date, 32 such groups have been defined¹¹. In contrast to the PaLoc, for which several truncated versions are known, few variations of the CdtLoc (*cdtR*, *cdtA* and *cdtB*) have been reported. CdtLoc is present either as a whole- or a single-truncated version and is replaced by a 68 bp sequence in the chromosomal location of the *cdt*-negative strains¹⁰. By analysing the *tcdR* and *cdtR* sequences, we assessed the variability of PaLoc and CdtLoc to study the genetic relatedness of the RA09-70, SA10-050 and CD10-165 strains among the *C. difficile* strains, as previously detailed³⁹.

When we searched for the homology of the TcdR and CdtR proteins between the reference strain CD630 and their homologs in a wide range of PCR-ribotype strains, we found that both regulators were highly conserved, with sequence identities of >97% and >95%, respectively (Table 2 and Table S1). In contrast, TcdR of the RA09-70 and SA10-050/CD10-165 strains shared only 73% and 75%, respectively, amino acid identities with TcdR of all of the other PCR-ribotype strains that were selected in this study, including the reference CD630 strain (Table 2 and Table S1). Moreover, the amino acid identity of CdtR present in the SA10-050 and CD10-165 strains varies from 59% to 62% compared to CdtR of all of the studied CDT-positive strains (Table 2 and Table S1). Thus, the low identity of the TcdR and CdtR regulators between the RA09-70, SA10-050 and CD10-165 strains and the representative strains of the main PCR-ribotypes suggests that sequences of their PaLoc and CdtLoc must be distinct enough to consider a long-term divergence compared to those of the *C. difficile* strains that have been studied to date.

The holin-like protein BhIA/UviB: a substitute of TcdE? Based on the analysis of more than 1000 sequenced genomes of toxigenic *C. difficile* strains^{8,22}, we observed that a holin-encoding gene is always present and corresponds to the class I holin TcdE⁵ for the majority of *C. difficile* strains. Recently, Elliot and colleagues¹⁵ showed in the *C. difficile* ES130 strain (Clade 5) that *tcdE* was replaced in the PaLoc by the *tcsE* gene, encoding a holin-like protein that is potentially required for secretion of *Clostridium sordellii* cytotoxin TcsL^{8,40}. In the RA09-70 strain, we found that *tcdE* is substituted by a gene encoding a protein that contains a full-length domain homologous to bacteriophage holin protein BhIA/UviB. This putative holin protein of 71 amino acids has a single N-terminal transmembrane domain (TMD) and several positively charged amino acids in the C-terminus, which are structural features of class III holins (Fig. S4). Surprisingly, this protein shares no significant homology with TcdE but has 34% and 31% amino acid identities with UviB of *C. perfringens* and BhIA of *B. subtilis*, respectively. UviB was assumed to play a role in bacteriocin secretion⁴¹, whereas BhIA, which was characterised as a new type of holin-like protein⁴², is likely required for the secretion of the BlyA, an N-acetylmuramoyl-L-alanine amidase that is associated with SP β -phage-mediated cell lysis³⁵. To annotate the putative holin-like protein of RA09-70, we constructed a phylogenetic tree by comparing the RA09-70 protein with both BhIA homologues in *Bacillus* species (*B. subtilis*, *B. laterosporus*, *B. licheniformis* and *B. pumilus*) and UviB homologues in *Clostridium* species (*C. perfringens*, *C. botulinum*, *C. tetani* and *C. sporogenes*). We found that the RA09-70 protein belongs to the UviB subtree (Fig. S4) and therefore was annotated as UviB.

Then, we sought to evaluate whether RA09-70 UviB has a holin-like activity by complementing an *E. coli* λ lysogen that is defective for the λ holin as previously performed for TcdE⁵. As previously mentioned, by forming holes in the host cell membrane, holin allows a prophage-encoded endolysin to cross the membrane and to attack the murein, resulting in cell lysis and in the release of phage particles³⁶. To test the holin activity of RA09-70 UviB, we cloned the *uviB* gene in a heat-inducible expression plasmid that we used to complement *E. coli* λ lysogen (cI₈₅₇-Sam7), which has a functional endolysin gene but a nonsense mutation in its holin gene (Sam7)⁵. To confirm the functionality of this system, we expressed the λ holin (S¹⁰⁵) in *E. coli* MC1063 λ (cI₈₅₇-Sam7) and observed that bacterial lysis is completed 45 minutes after heat induction (Fig. 5). In addition, no lysis was observed after the induction of the *E. coli* λ lysogen carrying the empty vector. When expressed in *E. coli* MC1063 λ (cI₈₅₇-Sam7), UviB induced

Figure 5. Testing holin function of UviB in *E. coli*. Lysis curves of *E. coli* λ lysogenic culture carrying λ cI₈₅₇Sam7 (full) or λ Cmr Δ (SR) (dotted) and plasmid expressing in trans S¹⁰⁵ (T+), TcdE and UviB. *E. coli* λ cI₈₅₇Sam7 carrying pBRQ was used as negative control (T–). Curves are a compilation of 5 independent cultures (3 for UviB–).

complete bacterial lysis within fifteen minutes after heat induction, similarly to TcdE (Fig. 5). As for the λ holin (S¹⁰⁵), lysis induced by the expression of UviB required the expression of the λ endolysin. In fact, the expression of UviB and TcdE in the *E. coli* λ Cmr Δ (SR) strain carrying a deletion in the holin and endolysin genes did not cause lysis (Fig. 5). These results indicate that the lysis of *E. coli* was not due to the over-expression of UviB, thereby demonstrating that UviB functions as a phage holin, similar to TcdE.

These results confirm that a holin-like gene is always present in the PaLoc in addition to the TcdR-encoding gene, as all known toxigenic strains that have been sequenced to date possess either TcdE or substitutes of TcdE, such as TscE¹⁵ or UviB (this study). These findings reinforce the importance of holin-like proteins in *C. difficile* toxin secretion⁵.

Discussion

The under-diagnosis of *C. difficile* infections across Europe is due in part to the use of sub-optimal detection methods³ and possibly to the emergence of new variant strains that cannot be detected by the diagnostic tools that are available in different laboratories. We demonstrated in this work through the characterisation of new *C. difficile* variants that standard diagnostic assays may be impeded by changes in the PaLoc and CdtLoc. This event may result from major sequence variations in toxin genes that do not match the primers that are used in certain molecular methods or from the complete deletion of *tcdA*^{15,16} or *tcdB*. In the present study, we describe a clinical isolate A⁺B⁻, a finding that to the best of our knowledge has never been reported before for the many *C. difficile* strains that have studied. Importantly, we present here unique evidence that the PaLoc can be located at other sites of the genome than is usually the case for classic *C. difficile* strains.

The inconsistent results of the molecular and immunoassays that were performed in the three strains of this study perfectly illustrate that no single test could completely characterise all *C. difficile* isolates. Particularly, the absence of a diagnostic test for *cdt* genes leads to underestimate the presence of CdtLoc among toxigenic strains. In contrast, a cell cytotoxicity assay was the only diagnostic test that consistently detected the cytopathic effect that was caused by the production of toxin B from strains SA10-050 and CD10-165. The presence of toxigenic A⁺B⁻ strains, such as RA09-070, whose changes in amino acid sequence could limit the use of commercial immunoassays, would not even be diagnosed by cell cytotoxicity assays. Thus, our results underline the potential impact of target sequence modification in clinical strains on the results of routine diagnosis assays. The suboptimum diagnosis of such atypical strains may have direct implications for patients who will not received appropriate treatment and for who contact precautions to avoid nosocomial transmission will not be implemented. Although these new *C. difficile* variant strains seems to be very uncommon in clinical practice, our data suggest to use diagnostic tests that detect both toxins A and B or nucleic acid amplification assays targeting both *tcdA* and *tcdB* genes.

Figure 6. Model of the PaLoc Evolution from “Mono-Toxin PaLoc” to “Bi-Toxin PaLoc”. Genes are identified by their color. (A) Fusion of two mono-toxin PaLoc sequence to form a single bi-toxin PaLoc. Nucleotide alignments of both SA10-050/CD10-165 *cwlH* gene and RA09-70 *uviB* gene to the intergenic region between *tcdE* and *tcdA* of CD630 are represented by colored column with their percent identity. (B) Model of (C). *difficile* PaLoc evolution.

The whole genome sequence analysis of the RA09-70 and SA10-050/CD10-165 strains allowed us to demonstrate for the first time that the PaLoc can be located at different sites in the *C. difficile* genome. Moreover, we showed that elements inserted within the classical PaLoc integration site of these strains belong to different clades defined based on the flanking chromosomal sequences of the PaLoc^{8,43}. We also show that insertion in the element of the RA09-70 strain is similar to the Clade 5 non-toxinogenic strains⁸ (Fig. 4b), which usually produce binary toxins¹⁵. However, although we clearly localised the PaLoc variant of this strain next to the *spoVAE* gene (CD630_07750) (Fig. 4b), we could not find genes of the CdtLoc. We deduced from this analysis that the PaLoc-replacing element of the SA10-050/CD10-165 strains belongs to Clade C-I (Fig. 4c), known to produce neither toxin A nor toxin B³. Accordingly, these strains seem to represent the first examples of a toxinogenic (A⁻B⁺) strain in this clade (Fig. 4c).

The identification of variable-sized PaLoc, integrated at different sites of the *C. difficile* genome, raised intriguing questions regarding PaLoc evolution, which seems to have been leading to the classical PaLoc observed in the majority of *C. difficile* strains.

Based on the obtained sequences of the PaLoc variants from the three strains studied here, we suggest that the classical PaLoc, *i.e.*, a “Bi-Toxin PaLoc”, might be the result of a fusion of two “Mono-Toxin PaLoc” from ancestral Clostridia strains through multiple independent PaLoc acquisitions, leading to the stabilisation of the “Bi-Toxin PaLoc”. Our hypothesis is supported by the sequence similarities that were observed between the *cwlH* and the *uviB* genes present within the PaLoc of the SA10-050/CD10-165 and the RA09-70 strains, respectively, and the intergenic region between *tcdE* and *tcdA* genes within the PaLoc of the reference strain CD630 (Fig. 6A). Indeed, the 5' part of the endolysin encoding gene, *cwlH*, is highly similar (80% nucleotide identity) to the pseudogene CD630_06620 next to the *tcdE* gene of the CD630 PaLoc (Fig. 6A and Fig. S5). The complete match of CD630_06620 with the *cwlH* gene of SA10-050/CD10-165 strains confirmed its annotation as a phage-like endolysin fragment-encoding gene⁴⁴. In addition, the C-terminal encoding part of *uviB* matches (85% nucleotide identity) a 136bp intergenic region just upstream of the *tcdA* gene of the CD630 PaLoc (Fig. 6A and Fig. S5). This second match is localised immediately after the first match that was observed between the gene encoding *cwlH* and CD630_06620 (Fig. 6A). Hence, the two regions present side by side in the CD630 PaLoc that partly overlap the *cwlH* and the *uviB* from the PaLoc variants are very likely remnants of the fusion of

two “Mono-toxin PaLoc” regions that gave rise to a single “Bi-Toxin PaLoc”. During this fusion, only one holin (TcdE) was conserved, and the endolysin (CwlH) seems to have been removed to avoid its potentially lethal effects on the membrane of bacteria⁵. Throughout the evolution of *C. difficile* strains, variations in the PaLoc could derive from the “Bi-Toxin PaLoc” by sequence changes or deletions of the toxin genes (Fig. 6B).

Furthermore, we also performed an *in silico* analysis of the *tcdR* promoter regions of the CD630, RA09-70 and CD10-165/SA10-050 strains. We found that the regulator and sigma factor binding site patterns of CD630 and CD10-165/SA10-050 strains were closer than the similarity with RA09-70 (Fig. S6). This result adds one more argument to our “fusion model” (Fig. 6), where the *tcdR* gene of the “Bi-toxin PaLoc” (CD630) comes from the “Mono-toxin B PaLoc” (CD10-165/SA10-050) rather than from the PaLoc of RA09-70. Such a PaLoc evolution model anticipates that diverse PaLoc forms had to be transferred among *C. difficile* strains, a finding that has recently been demonstrated experimentally for the CD630 PaLoc by a conjugation-like mechanism⁴⁵. In this scenario, the *tcdC* gene, which is not present in the “Mono-toxin PaLoc” strains, must have been provided by another event because *tcdR* and *tcdC* genes have evolved divergently in the studied strains³⁹.

The same model could be suggested for other pathogenic clostridia, such as *C. sordellii*, harbouring a similar PaLoc to that of the classical Bi-toxin PaLoc of *C. difficile*⁴⁶. Recently, Couchmam *et al.*⁴⁷ found that a small number of *C. sordellii* strains carry PaLoc variants located on plasmids (pCS1-1 and pCS1-3, Fig. S7), substituting 14 genes of the pCS1 backbone. When we compared the gene content and organisation within the PaLoc of *C. sordellii* and *C. difficile* (Fig. S7), we observed in addition to the toxin similarity (*tcdB/tcsL* and *tcdA/tcsH*) that both species have the same PaLoc accessory genes, i.e., genes encoding a transcriptional regulator (*tcdR* and *tcsR*), a holin-like protein (*tcdE* and *tcsE*) and, when compared to the *C. difficile* strains CD10-165/SA10-050, an amidase (*cwlH*) (Fig. S7). Interestingly, among the described PaLoc variants, one has a truncated form of the *tcsH* gene, indicating possible genetic polymorphisms within the *C. sordellii* PaLoc region, as shown for *C. difficile*. Therefore, it seems reasonable to expand the *C. difficile* model to the PaLoc of *C. sordellii*, but more sequenced *C. sordellii* PaLoc types are required to prove it.

Together, this work supports a substantial body of evidence that argues for a scenario in which the classical “Bi-Toxin PaLoc” was generated by a fusion of two “Mono-Toxins PaLoc” (Fig. 6) and provides the basis for investigating the involved molecular mechanisms. In addition, the synteny between the *C. difficile* and *C. sordellii* PaLoc genes as reinforced by the presence of the *C. sordellii* holin-like gene *tcsE* in the PaLoc of the *C. difficile* strain ES130¹⁵ supports the idea of a common ancestor of the clostridial PaLoc.

Acknowledgements

Acknowledgement to the LABGeM team and the National Infrastructure « France Genomique ». High-throughput sequencing has been performed on the Genomics Platform, member of « France Génomique » consortium (ANR10-INBS-09-08). The work was supported by funds from Institut Pasteur and Grant ERA-PTG/SAU/0002/2008 (ERA- NET PathoGenoMics) for BDup and M.M. We thank Dr. Brosch Roland and Dr. Peltier Johann for comments and corrections of the manuscript.

Author Contributions

B.H., Bdum and V.L. contributed sources of *C. difficile* DNA. T.D., A.H., A.L., C.T. and A.P. designed and performed the experiments. V.L., C.E. and A.P. performed the routine diagnostic tests. M.M., L.M. and

C.B. performed DNA sequencing and bioinformatic data analyses. M.M., C.E., B.Dup. and F.B. wrote the manuscript with contributions from all other authors.
