The uncoupled ATPase activity of the ABC transporter BtuC₂D₂ leads to a hysteretic conformational change, conformational memory, and improved activity

Nurit Livnat-Levanon¹, Amy I. Gilson², Nir Ben-Tal³ & Oded Lewinson¹

ABC transporters comprise a large and ubiquitous family of proteins. From bacteria to man they translocate solutes at the expense of ATP hydrolysis. Unlike other enzymes that use ATP as an energy source, ABC transporters are notorious for having high levels of basal ATPase activity: they hydrolyze ATP also in the absence of their substrate. It is unknown what are the effects of such prolonged and constant activity on the stability and function of ABC transporters or any other enzyme. Here we report that prolonged ATP hydrolysis is beneficial to the ABC transporter BtuC₂D₂. Using ATPase assays, surface plasmon resonance interaction experiments, and transport assays we observe that the constantly active transporter remains stable and functional for much longer than the idle one. Remarkably, during extended activity the transporter undergoes a slow conformational change (hysteresis) and gradually attains a hyperactive state in which it is more active than it was to begin with. This phenomenon is different from stabilization of enzymes by ligand binding: the hyperactive state is only reached through ATP hydrolysis, and not ATP binding. BtuC₂D₂ displays a strong conformational memory for this excited state, and takes hours to return to its basal state after catalysis terminates.

Under various physiological circumstances enzymes need to be active and remain fully functional for a long time. Such is the case of housekeeping enzymes that are known to be constantly active for several hours or even days^{1–6}, or any enzyme with a long half-life that performs an essential cellular task.

An analogy is often drawn between man-made machines and enzymes: both consume energy, perform work, and have moving parts. Quite routinely we observe that the performance of man-made machines deteriorates over time, especially when used extendedly. Intuitively, one would predict that a molecular machine, an enzyme, would also be adversely affected by prolonged work. To our knowledge, this expectation was never experimentally tested. Here, we studied the effects of prolonged activity on the stability and function of one enzyme, an *E. coli* ABC transporter.

From bacteria to man, ATP Binding Cassette (ABC) transporters comprise a very large and diverse protein super family^{7–11}. They are involved in many physiological processes such as signaling, cell division, antigen presentation, and solute translocation^{12–14}. ABC transporters are also the focus of much clinical research, being directly implicated in human disease, resistance of tumors to chemotherapy, bacterial resistance to antibiotics, and bacterial pathogenesis and virulence^{8,14,15}. ABC transporters generate substrate concentration gradients across biological membranes at the expense of ATP hydrolysis^{16,17}. One would expect that the energy input (ATP hydrolysis) would be tightly coupled to the output of work (substrate translocation). However, with a handful of exceptions^{18,19}, ABC transporters are notorious for having high levels of ATPase activity in the absence of their transportable substrate. Thus, the enzyme is active, constantly hydrolyzing ATP without generating a substrate concentration gradient. This uncoupled ATPase activity has been observed in mammalian, yeast, and bacterial

systems, with exporters and importers, in membrane vesicles, liposomes, and lipid nanodiscs^{16,17,20–23}. The origin of this high basal ATPase activity is unknown. One possibility is the presence of unidentified endogenous substrates (e.g., lipids) that stimulate the ATPase activity of the transporters. This might be the case for the highly pleiotropic yeast exporter Pdr5 that recognizes hundreds of different compounds^{24,25}. However, this possibility is unlikely in the case of a highly specific importer such as the vitamin B₁₂ importer²⁶. Here, we studied the effects of constant, uncoupled ATP hydrolysis on the structural and functional integrity of the *E. coli* vitamin B₁₂ transporter BtuC₂D₂. We let BtuC₂D₂ hydrolyze ATP for minutes, hours, or days and followed its activity levels.

The results are very surprising: constant and prolonged ATP hydrolysis drives a hysteretic conformational change that leads to a hyperactive state, in which BtuC₂D₂ is more active than it was to begin with. This hyperactive state can only be reached via ATP hydrolysis and not by ATP binding. Thus, the phenomenon we describe here is very different from stabilization of proteins by ligand binding.

Results

The effects of prolonged activity on BtuC₂D₂. To study the effects of prolonged activity on BtuC₂D₂ we purified the core transporter (ATPase+permease) and then dialyzed it in a micro-dialysis tube against a buffer containing detergent and a mixture of *E. coli* lipids and L- α -Phosphatidylcholine from egg yolk (see methods for details). The lipids are added to prevent protein delipidation and the detergent prevents formation of sealed liposomes thus circumventing accessibility issues. Initially, all incubations/conditioning of BtuC₂D₂ were performed in this lipid/detergent environment. In later experiments, conditioning of BtuC₂D₂ was also performed in the absence of detergent, using reconstituted protein-lipid nanodiscs (see below).

Since our initial goal was to test whether constant activity accelerates the deterioration rate of BtuC₂D₂ we first tested two simple conditioning regimes, termed “resting” and “working”. In the “working” regime, the protein is dialyzed against the lipid/detergent buffer that contains magnesium and ATP. ATP is present at near saturating concentration (100 μ M, 90% saturation, Supplementary Fig. 1A), and similar results were obtained when 250 μ M ATP was used (94% saturation). Due to the high basal activity of BtuC₂D₂ the protein constantly hydrolyzes ATP^{16,17}. The large volume of the buffer (1000-fold excess), the molar excess of ATP over BtuC₂D₂ (12,000:1), and the buffer’s periodic replacement ensures a constant supply of fresh ATP. We also verified that during the time course of the experiment ATP is not depleted and that there is no measurable inhibition by the hydrolysis products (Supplementary Fig. 1B). The “resting” regime is identical, containing magnesium but omitting ATP. Therefore, the protein sits idle during the conditioning.

At intervals, we withdrew samples, and to remove possible aggregates, we centrifuged them first at medium speed (10 min, 17,000xg) and then at high-speed (30 min, 150,000xg). Using either centrifugation speed we found that hardly any protein was pelleted, indicating little to no aggregation, and therefore routinely used the lower speed spin. We also used size exclusion chromatography to assess the aggregation state of the rested and worked samples and found that both lacked significant aggregation (Supplementary Fig. 2A). We later found that the protein that had aggregated and precipitated during the incubations could not be removed simply by pipetting (see later).

We then measured how well BtuC₂D₂ that avoided aggregation retained its ATPase activity under the ‘resting’ or ‘working’ regimes. The results were very surprising: when we measured the total ATPase activity remaining in solution we found it to be much lower for the protein that had rested (Fig. 1A). Two factors contributed to the faster decline in total ATPase activity of the resting protein. First, less of the resting protein remained in solution over time. This was readily observed by Coomassie staining of SDS-PAGE (Fig. 1B) and by quantification of protein amounts using a detergent/lipid compatible protein assay (Fig. 1C). We did not observe protein degradation in either of the incubation regimes. Rather, we found that BtuC₂D₂ aggregates and precipitates during the incubations, and could only be extracted from the dialysis tubes with 10% SDS at 55 °C. In-line with its lower amounts of soluble protein, 10% SDS extracted more protein from the dialysis tube of resting BtuC₂D₂ (Supplementary Fig. 2B). A band of ~60 kDa appeared in these SDS-extracted samples. This band, which likely represents SDS-resistant higher molecular weight oligomers was much more prominent in the rested sample.

However, the decline in the amount of rested BtuC₂D₂ did not fully account the loss of activity: When we calculated the specific ATPase activity of the rested BtuC₂D₂ molecules we found that they gradually become inactive (Fig. 1D). Thus, with time, even those resting BtuC₂D₂ molecules that avoid precipitation and aggregation become inactive. This lower specific activity of rested BtuC₂D₂ is likely due to local unfolding events that compromise catalysis but do not yet lead to complete unfolding and aggregation.

In contrast, the working molecules that persisted in solution fully retained their specific ATPase activity throughout the 4 days of the experiment (Fig. 1D). Therefore, not only that the working molecules remain in solution longer (Fig. 1B, C), the specific activity of the persisting molecules is higher (Fig. 1D). The experiment shown in Fig. 1 was conducted in 28 °C, yet we observed similar trends also at 20 and 37 °C, with the rates of activity loss accelerating with increasing temperatures (Supplementary Fig. 3). The working protein was also much superior to the idle one in the closely related functions of GTP and CTP hydrolysis (Supplementary Fig. 4). This is perhaps not surprising as hydrolysis of ATP, GTP, and CTP likely takes place at the same active site (the nucleotide binding domain of the transporter) and probably by a similar mechanism²⁷.

We next tested rested and worked BtuC₂D₂ molecules for a function that occurs ~60 Å away from the site of ATP hydrolysis: binding of BtuF, the system’s substrate binding protein (SBP)^{17,26,28}. Like all ABC importers BtuC₂D₂ must associate with its cognate SBP since it is the latter that binds the substrate and delivers it to the transporter. We measured the interaction between BtuC₂D₂ that had worked or rested at 28 °C and BtuF using Surface Plasmon Resonance²⁹. We loaded identical amounts (by mass) of worked or rested BtuC₂D₂ onto a bio-sensor chip and then washed the chip 50,000-fold to remove any residual ATP. As shown (Fig. 2A), BtuC₂D₂ that had hydrolyzed ATP for 7 days at 28 °C robustly interacted with BtuF, while the 7-days rested protein was completely inactive. The 2-days and 4-days rested BtuC₂D₂ molecules interacted with BtuF but at reduced levels

Figure 1. Activity and stability of the working and resting BtuC₂D₂. (A) BtuC₂D₂ was incubated at 28 °C under the resting (circles) and working (squares) regimes. At the indicated times equal VOLUMES were removed from each sample and assayed for hydrolysis of 1mM ATP. (B) Equal volumes from the samples used in A were subjected to reducing SDS-PAGE and stained by Coomassie blue. The two gels were identically run, stained, and imaged. (C) The protein concentration of the samples used in A was determined using a Lowry-based lipid and detergent compatible protein assay. Resting regime: circles, working regime: squares. (D) Specific ATPase activity under the resting (circles) and working (squares) regimes. Each data point shown in panel (A) was standardized by the remaining protein concentration shown in (C). The experiments were repeated at least three times and error bars represent standard deviations of technical triplicates of a single experiment.

(Fig. 2A), in agreement with their reduced ATPase activities (Fig. 1D). Since identical amounts of non-aggregated rested or worked BtuC₂D₂ were loaded to the biosensor chip this shows that also with respect to BtuF binding the rested protein has a much-reduced specific activity.

We then measured the vitamin B₁₂ transport activity of rested or worked BtuC₂D₂. For this we incubated BtuC₂D₂ for 3 days at 28 °C at the working or resting conditions, determined the amount of remaining protein, and then reconstituted equal protein amounts into liposomes. We also verified that equal amounts of rested or worked BtuC₂D₂ were indeed incorporated into the liposomes by washing the liposomes with sodium carbonate (to remove peripherally associated protein) and then subjecting them to sucrose flotation assays (to differentiate between aggregates and membrane-inserted protein). As shown in supplementary Fig. 5A,B the protein content of liposomes reconstituted with worked or rested BtuC₂D₂ was very similar. We incorporated an ATP-regenerating system in the lumen of the liposomes, and BtuF and ⁵⁷Co-labeled vitamin B₁₂ were added externally (see methods). BtuC₂D₂-mediated uptake of vitamin B₁₂ was then measured using the rapid filtration method as others and we have performed in the past^{16,17}. As shown, the transport activity of BtuC₂D₂ that had been incubated for 3 days under the working regime was 3–4 folds greater than that of the protein that had rested (Fig. 2B). As with the ATPase assays (Fig. 1D) and SPR experiments (Fig. 2A), this experiment shows that the specific activity of worked BtuC₂D₂ is higher than that of rested BtuC₂D₂.

In the experiments described above the conditioning/incubation of BtuC₂D₂ was conducted in a lipid/detergent solution. We next tested if a similar process occurs in a more native-like membrane environment. For this we reconstituted BtuC₂D₂ into lipid nanodiscs using previously established protocols^{30,31}. Then, we subjected BtuC₂D₂-nanodiscs to the same working and resting regimes. Importantly, unlike the experiments described above, this incubation was performed in the absence of detergent. Fig. 2C shows that also in the absence of detergent, and in a membrane-mimetic environment the protein that had worked remained much more active than the one that had rested.

Figure 2. (A) Surface plasmon resonance analysis of the interaction between BtuF and BtuC₂D₂ that had rested or worked for the indicated times at 28 °C. At time zero, 0.2 μM apo BtuF is injected for 90 seconds over identical amounts of worked or rested BtuC₂D₂. (B) Vitamin B₁₂ uptake by BtuC₂D₂ that had rested or worked. BtuC₂D₂ was incubated for 3 days at 28 °C at the working or resting conditions, and consequently equal protein amounts were reconstituted into liposomes. Uptake of 5 μM Co⁵⁷ vitamin B₁₂ (in the presence of 1 μM BtuF) by empty liposomes (circles), rested BtuC₂D₂ liposomes (squares), or worked BtuC₂D₂ liposomes (triangles) was measured using the rapid filtration method. Error bars represent standard deviations of three experiments. (C) ATPase activity of BtuC₂D₂ that was reconstituted into nanodiscs and then incubated for 3 days at 28 °C at the working (black trace) or resting (grey trace) conditions. The experiments were repeated at least three times and error bars represent standard deviations of technical triplicates from a single experiment.

In summary, the data presented so far strongly demonstrates that prolonged activity does not accelerate the deterioration rate of BtuC₂D₂. We find this unexpected considering the constant conformational changes associated with ATP hydrolysis, flux of energy, and production of heat.

Nucleotide binding stabilizes BtuC₂D₂. When hydrolyzing ATP BtuC₂D₂ repeatedly cycles through several nucleotide-bound conformations. Therefore, a likely explanation for the increased stability in the working conditions is that one (or several) of these conformations is more stable than the apo state. Thermodynamic stabilization of enzymes by their ligands is a very common phenomenon and was also observed in ABC transporters and other ATPases³². We therefore tested if one of the intermediate states of ATP hydrolysis (ATP-bound, transition state, or ADP-bound³³) is responsible for the stabilization of ATP-hydrolyzing BtuC₂D₂. To test this, we conducted experiments where, in addition to the resting and working regimes, we included conditions that mimic the nucleotide-bound intermediates (see methods for details). Indeed, relative to the apo ('resting') state, in all of the nucleotide bound states, more protein persisted in solution over time (Fig. 3A). To measure the activity of the samples that had been pre-treated with nucleotide (worked, ATP-bound, transition state, or ADP-bound) we first removed the nucleotides with which they were incubated (see methods). We also verified by spectroscopy and gel filtration chromatography that the nucleotides had indeed been removed (Supplementary Fig. 6A), and that there is no aggregation (Supplementary Fig. 6B). Figure 3B shows that relative to the apo state ('resting' protein), all of the nucleotide bound states better preserve the BtuF binding activity of BtuC₂D₂. Taken together, these experiments show that the stabilization of BtuC₂D₂ under conditions of constant ATP hydrolysis is probably due to nucleotide binding.

Only ATP hydrolysis, and not binding, leads to a hyperactive state. So far, the data show that relative to the apo state, BtuC₂D₂ is more stable when constantly hydrolyzing ATP, and that this stabilization is

Figure 3. Nucleotide binding stabilizes BtuC₂D₂. (A) BtuC₂D₂ was incubated at the indicated conditions at 37°C for 24 or 48 hours, as indicated. The amount of protein that remained in the soluble fraction visualized by Coomassie staining of reducing SDS-PAGE. The molecular weight marker is a cut and paste from the exact same gels. (B) BtuC₂D₂ was incubated for 1 day at 37°C under the following regimes: resting (green), vanadate-trapped transition state (gray), ADP-bound (magenta), ATP-bound (red), or working (black). Also shown for comparison is the fresh (naïve) protein (blue). The nucleotides were removed by desalting and identical amounts (by mass) from each treatment were loaded onto an SPR biosensor chip. Following their immobilization the samples were washed ~50,000-fold to remove any residual ligands. At time zero 0.1 μ M substrate-free BtuF was injected over all samples for 180 seconds. The experiments were repeated at least three times.

most likely due to nucleotide binding. These findings by themselves are perhaps interesting but not very surprising. What we found very unexpected is that BtuC₂D₂ that had worked for several hours bound more BtuF than the freshly prepared BtuC₂D₂ from which it originated (Fig. 3B compare black and blue curves). Importantly, pre-incubation of BtuC₂D₂ in any of the nucleotide-bound states did not recapitulate this ‘improvement’ effect (Fig. 3B, grey, magenta, and red curves, and see also below). Again we stress that the activity measurements were conducted after removal of nucleotides (Supplementary Fig. 6). This phenomenon was highly robust and always repeated itself, and was observed for the interaction of BtuC₂D₂ with both holo and apo BtuF (Fig. 4A,B). The degree of the ‘improvement’ varied between 35–60%, depending on the preparation. The data presented in Fig. 4 show ~40% improvement of the worked sample ($P = 7.5 \times 10^{-6}$, $n = 5$, using a single preparation), with no significant changes in the equilibrium or pre-equilibrium constants (K_D , k_{on} , k_{off}) of the interaction (Table 1). The only parameter that significantly differed between the naïve protein and BtuC₂D₂ that had worked was R_{max} , representing the maximal active binding sites (BtuC₂D₂ molecules that are able to bind BtuF). In these experiments identical amounts of freshly prepared and worked BtuC₂D₂ were present on the adjacent flow-cells (Supplementary Fig. 7). Since only the maximal binding changed, and not the kinetic constants, this means that relative to freshly prepared protein, a greater percentage of the BtuC₂D₂ molecules that had worked are in a conformation that binds BtuF (*i.e.*, have higher specific activity with respect to BtuF-binding).

Docking of BtuF to BtuC₂D₂ is essential for transport and this step immediately precedes translocation of vitamin B₁₂. On the one hand, BtuC₂D₂ that had worked showed unchanged specific ATPase activity (Fig. 1D). On the other, it displayed greater specific activity with respect to BtuF-binding (Fig. 4A,B). We therefore tested whether this improved BtuF-binding activity might also be translated into accelerated transport rates. To test this we incubated BtuC₂D₂ for 7 hours at 37°C under the ATP-bound or ATP-hydrolyzing conditions, and then used a rapid reconstitution protocol (see methods for details) to reconstitute pre-treated or naïve BtuC₂D₂ into liposomes. We verified that an equal amount of BtuC₂D₂ was incorporated into the liposomes (Supplementary Fig. 5C–E, Supplementary Fig. 8), and that the preparations had similar proportions of right-side-out or inside-out facing BtuC₂D₂ (Supplementary Fig. 8). We then measured ⁵⁷Co-labeled vitamin B₁₂ uptake into liposomes as described for Fig. 2. As shown (Fig. 4C), in agreement with its improved BtuF-binding capacity, the vitamin B₁₂ uptake rate of BtuC₂D₂ that had hydrolyzed ATP for 7 hours was ~60% faster than its fresh precursor. Importantly, incubation of BtuC₂D₂ in the ATP-bound state did not change its rate of vitamin B₁₂ uptake (Fig. 4C), in line with its unchanged BtuF-binding activity (Fig. 3B). Collectively, these experiments show that although binding of ATP acts to stabilize BtuC₂D₂ and slow down its deterioration (Fig. 3A), it does not promote an increase in activity levels (relative to the fresh protein). In comparison, ATP hydrolysis by BtuC₂D₂ promotes stability (probably due to

Figure 4. BtuC₂D₂ that has worked for several hours outperforms its naïve precursor. (A) Identical amounts of fresh BtuC₂D₂ (red curves) or the same preparation that has worked for 7 hours (blue curves) were loaded onto an SPR chip. At time zero a series of five apo BtuF concentrations was injected, as indicated next to each curve: (1) 0.1 μ M, (2) 0.175 μ M, (3) 0.25 μ M, (4) 0.75 μ M, (5) 2 μ M (B) Same as in (A) only holo BtuF was injected at 0.5 μ M or 1 μ M (as indicated) in the presence of 200 μ M vitamin B₁₂. (C) Uptake of ⁵⁷Co vitamin B₁₂ into empty liposomes (circles), liposomes reconstituted with fresh BtuC₂D₂ (squares), BtuC₂D₂ that was pre-incubated in the ATP-bound state for 7 hours (crosses), or with BtuC₂D₂ that has worked for 7 hours (triangles). (D) Identical amounts of fresh BtuC₂D₂ mutant E159Q (red curve) or the same preparation that was incubated for 7 hours at the ATP-hydrolyzing conditions (blue curve) were loaded onto an SPR chip. At time zero 0.5 μ M apo BtuF was injected. The experiments were repeated at least three times and error bars in (C) represent standard deviations of three experiments.

Rmax (Ru)	67.7 ± 1.8	93.3 ± 1.4	9.20E-06

Table 1. Kinetic rate constants (determined by SPR) for the interaction of apo BtuF with fresh BtuC₂D₂ or BtuC₂D₂ that had worked for 7 hours. Rmax describes the maximal number of binding events and is given in response units (Ru). Errors represent standard deviations of five independent experiments.

the dwell time in the ATP-bound state), but also leads to increased activity. The notion that only ATP-hydrolysis, and not ATP binding, leads to a more active state is also supported by experiments performed with the E159Q mutant of BtuC₂D₂. This mutant binds ATP but cannot hydrolyze it, yet interacts normally with BtuF¹⁶. However, when we incubated this mutant under the working regime we did not observe an increase in its BtuF-binding activity (Fig. 4D). This shows that the working conditions themselves, without catalysis, cannot explain enhanced activity. With wild type BtuC₂D₂ we very reproducibly observed that ATP binding has a stronger stabilizing

Figure 5. Long-term memory of BtuC₂D₂. Freshly prepared BtuC₂D₂ (time zero) was incubated under the working conditions at 37 °C (in the absence of BtuF). At the indicated intervals samples were withdrawn, ATP was removed by microfiltration, and BtuF-binding was measured by SPR. After 5 hours ATP was removed from all of the remaining volume and the protein was incubated under the idle conditions (at 4 °C, to avoid idleness-associated detrimental effects) for another 2.5 hours, during which samples were removed and BtuF-binding was measured by SPR. Subsequently, AMP-PNP was added and BtuC₂D₂ was moved back to 37 °C (in the ATP-bound state the protein does not deteriorate at 37 °C). At the indicated intervals samples were withdrawn, the AMP-PNP was removed by microfiltration, and BtuF-binding was measured by SPR. Results are presented as percent change from the activity of the fresh, naïve protein. Error bars represent standard deviations of triplicates from two different experiments (n = 6).

effect than the working conditions (Fig. 3A, compare ATP-bound and worked after 48 hours). In contrast, when we tested the stability of the E159Q mutant in the different nucleotide-bound states we found that unlike the wild-type protein this mutant is equally stable under the working or ATP-bound conditions (Compare 48 hours of wild type in Fig. 3A to 48 hours of the mutant in Supplementary Fig. 9). Taken together these results further establish that the ATP-bound state is the most stable one, but only ATP hydrolysis leads to the hyperactive state.

BtuC₂D₂ displays a conformational memory. Importantly, the activity measurements shown in Figs 3 and 4 were conducted after termination of the working conditions (*i.e.*, removal of ATP-Mg). This means that the transporter remains in its excited state after the stimulus for its attainment has stopped. This phenomenon, termed “conformational memory” is not commonly observed but has been reported for horseradish peroxidase, MHC Class II molecules, cholesterol oxidase, a hairpin ribozyme, and antibody D2.^{34–38} Common to all these examples is that ligand binding drives the conformational memory. The lengths of the conformational memories is directly related to the relaxation time of the protein from its excited state to its basal state. Depending on the protein, the conformational memory can last from milliseconds³⁷ to hours³⁶. To our knowledge, BtuC₂D₂ presents the first example for a conformational memory that is achieved by repetitive completion of a catalytic cycle. We next investigated the timescale needed to produce conformational memory in BtuC₂D₂, and for how long the protein remains in its ‘excited’ mode after termination of ATP hydrolysis. Short incubations (seconds, minutes) in the working conditions did not produce any detectable changes in activity levels (Supplementary Fig. 10). Rather, we found that the conditioning takes several hours, but once attained, the protein remains in its excited state for at least two hours after termination of the working conditions (Fig. 5). Notably, BtuC₂D₂ that reached its excited state (following ATP hydrolysis) can be shifted back to its ground state by incubation in one of the conditions that does not promote the excited state (*i.e.*, the ATP-bound state, 8–18 hours in Fig. 5). Such a behavior is consistent with a population shift phenomenon, in which the protein resides in several folded conformations. These conformations are similar, yet not identical to one another, and have different activity levels. Ligand binding (as in previously described cases^{39,40}), or catalysis (unique for BtuC₂D₂) shifts the population towards one of these pre-existing conformations.

Prolonged ATP hydrolysis induces a slow conformational change (hysteresis). When constantly hydrolyzing ATP BtuC₂D₂ gradually becomes more active in terms of binding BtuF and transporting vitamin B₁₂, taking several hours to reach its highest activity level. Such time-dependent changes in activity levels are termed hysteresis, and explain the cooperative behavior of monomeric proteins and other enzymes that do not conform to Michaelis-Menten principles^{41–46}. This phenomenon originates from extremely slow conformational changes between (at least) two conformers that differ in their activity levels and/or kinetic properties⁴⁷. Introduction of ligand, or changes in ligand concentrations, shift the population towards the more active conformer(s)^{36,41,48}. When the isomerization between the conformers is slower than the enzymatic turnover rate, hysteresis is

Figure 6. A slow conformational change of BtuC₂D₂ measured by quenching of tryptophan fluorescence. (A) BtuC₂D₂ was incubated for 0 (black), 1 (red), 3 (magenta) or 7 hours (blue) under the working conditions. ATP was then removed by desalting, and all samples were diluted to the same concentration. 50 μ L of a 1 μ M protein solution were excited at 230–300 nm, emission was measured at 330 nm. (B) BtuC₂D₂ was incubated for 16 hours under the working or the ATP-bound conditions, as indicated. Fresh protein is shown for comparison as well. ATP was removed by desalting and 50 μ L of 1 μ M were excited at 275 nm (peak absorbance for BtuC₂D₂), emission was measured at 330 nm. The experiments were repeated at least three times and error bars represent standard deviations of technical triplicates of a single experiment. Also shown are P-values obtained by a Student's t-test (ns, not significant).

observed^{47,49}. To monitor possible conformational changes that occur over a time scale of hours, we let BtuC₂D₂ hydrolyze ATP for several hours, withdrew samples, removed the nucleotides used for the pre-conditioning, and measured the protein's tryptophan fluorescence. Figure 6A shows that during prolonged ATP hydrolysis BtuC₂D₂ undergoes a slow and gradual process of quenching of its 330 nm emission. Scanning the emission spectrum of the samples verified that this decrease in emission was not due to general red shift of the spectrum. Isomerization on a time scale of hours is perhaps not commonplace, but has been observed for MHC Class II molecules and for Ribozyme molecules^{36,38}. Importantly, incubation of BtuC₂D₂ in the ATP-bound state did not lead to a similar quench, and its 330 nm emission was more similar to that of the naïve protein (Fig. 6B).

Discussion

Intuitively, one might predict that a constantly working enzyme will deteriorate faster than an idle one. This is clearly not the case for BtuC₂D₂. The dwell time of the ATP hydrolyzing protein in the nucleotide-bound states likely accounts for this stabilization. Nevertheless, we still find this surprising: relative to the resting transporter or one that is trapped in a single nucleotide-bound state, working BtuC₂D₂ is much more exposed to destabilization. Unlike any single nucleotide-bound (trapped) state, it is not in equilibrium, and there is a constant flux of energy (ATP hydrolysis) that generates heat. The working protein is constantly dynamic, and likely samples a broader conformational space than the idle one. The higher dynamics present potential aggregation pitfalls and may lead to unstable conformations. Despite all these challenges, the working protein remains stable and active, much more so than the idle one. Although clearly advantageous from an evolutionary/biological perspective we find this surprising with respect to the material properties of a protein polymer.

Nucleotide binding has a strong stabilizing affect on BtuC₂D₂ (Fig. 3A,B), but it is insufficient to drive the hysteretic conformational change (Fig. 6B) and nor does it lead to the hyperactive state (Figs 3B, 4C,D, 5). BtuC₂D₂ provides the first example of hysteresis and conformational memory that are driven by catalysis, rather than by binding of a ligand to a specific conformation.

The hysteretic behavior of BtuC₂D₂ is also unique in another aspect: it presents the first example where conditioning of one function (here ATP hydrolysis) resulted in changes of activity levels of another (BtuF binding and vitamin B₁₂ transport). This is especially surprising since the ATPase activity itself does not change with the hysteretic conformational change. That conditioning of one domain in the protein affects another that is 50–60 Å away is likely due to the long-range allosteric interactions that occur in BtuC₂D₂^{50–53}. The opening and closing of the nucleotide binding domains (upon ATP hydrolysis) is transmitted via the coupling helices, through the trans-membrane domains, to the periplasmic loops, and finally to BtuF. Another noteworthy feature of BtuC₂D₂ is that the hysteretic 'excited' state is not a single conformation but rather an ensemble of conformations that carry out the complete catalytic cycle of vitamin B₁₂ transport. A highly simplified kinetic scheme describing the hysteretic behavior of BtuC₂D₂ is shown in Fig. 7. For simplicity, shown are only two conformations (E1 and E2): E1 binds BtuF with very low affinity and therefore hardly transports vitamin B₁₂; E2 is the form that interacts with BtuF

Figure 7. Kinetic scheme describing the hysteretic behavior of BtuC₂D₂. The model is written in terms of BtuC₂D₂ that cannot/hardly binds to BtuF (E₁) and BtuC₂D₂ that binds BtuF with high affinity (E₂). Arrows are bolded to reflect the relative reaction rates, and the red arrows depict the population shift that is affected by hysteresis. (K₁) and (K₂) are effective equilibrium association constants for binding of BtuF (represented as F) to BtuC₂D₂. K_s, K₃, and K_{sHYST} are effective equilibrium constants for the conformational change between E₁ and E₂, and are agnostic to whether the change proceeds in one step or through many intermediates. For simplicity we assume that E₁ is transport-incompetent and that E₂ is fully functional. The transport experiment shown in Fig. 4C shows that “worked” BtuC₂D₂ is approximately 50% more active than the fresh protein. Therefore, since only E₂ is transport-competent we suggest that in the initial “fresh” state of BtuC₂D₂ the ratio of E₂–E₁ is approximately 2:3 (K_s = 0.66). In the worked state, following the hysteretic conformational change, the E₂/E₁ ratio is shifted to 3:2, *i.e.*, K_{sHYST} = 1.5.

with high affinity and is thus transport-competent. However, E₁ and E₂ each represent an ensemble of conformations that are able to complete the cycle of ATP hydrolysis, yet interact differently with BtuF. The left side of Fig. 7 represents the ensemble of basal states, while the right represents the ensemble of hyperactive states. The latter are accessible to the transporter only via the hysteretic conformational change.

We have observed that continuous ATP hydrolysis increases BtuC₂D₂’s BtuF-binding activity. This improvement could proceed through two distinct mechanisms. First, ATP hydrolysis could gradually increase the BtuF-binding affinity of all BtuC₂D₂ molecules in the sample. In this case, SPR measurements would reveal an increase in BtuF binding affinity with no change of R_{max} for the worked sample over the fresh sample. Alternatively, ATP hydrolysis could drive a shift in the relative ratio of coexisting BtuF-incompetent (E₁) and BtuF-competent (E₂) conformations of BtuC₂D₂ (Fig. 7). In this case, SPR measurements comparing worked and fresh BtuC₂D₂ samples would detect no change in BtuF binding affinity while R_{max} would increase. As seen in Table 1, the second, population shift mechanism is consistent with experimental observation. The maximum number of binding events (R_{max}), increases from 67.7 in the fresh sample to 93.02 in the worked sample, a ~40% increase. From this data, we deduce that the population of BtuC₂D₂ molecules capable of binding BtuF increased by 40%. This is consistent in a shift in the ratio E₂/E₁ from 0.66 (2/3) in the fresh sample (Fig. 7, left) to 1.5 (3/2) in the worked sample (Fig. 7, right). The hysteretic conformational change is very slow, and occurs over several hours (Fig. 6). Likewise, attainment of the hyperactive state also proceeds over several hours (Fig. 5). In our view these two processes are linked and are practically synonymous. Since all other catalytic steps occur on a time-scale of seconds we believe that the rate-limiting step is the conversion between the E₁ and E₂ conformations. How common is hysteresis and conformational memory in proteins?

In addition to BtuC₂D₂ we tested two other ABC transporters (MetIN and ModBC) and found no evidence for hysteresis or conformational memory. It therefore seems that it is not a common feature of ABC transporters. We thoroughly surveyed the literature and found a handful of reported examples of enzymes/proteins that display conformational memory^{34–39}. However, we believe that this may be an underrepresentation that stems from technical limitations: when the isomerization is very slow and the conformational memory is long, bulk measurements can identify hysteretic behavior (herein and in MHC Class II molecules³⁶). However, faster isomerization that leads to a conformational memory that lasts seconds or milliseconds will often require single molecule measurements that are available for very few systems.

The *in-vivo* relevance of our observation with BtuC₂D₂ remains unknown: we do not know whether in the cell BtuC₂D₂ attains a hyperactive state following prolonged activity. However, it is tempting to tie our observations to a long lasting yet puzzling observation that BtuC₂D₂ has a very high basal ATPase activity in the absence of its transported substrate^{16,17}. In light of the results reported here this constant activity may maintain its structural and functional integrity and keep it in a more active state. Considering the limited capacity of membranes to contain proteins, the existence of such an inherent mechanism that stabilizes and improves the activity of membrane-embedded enzymes only for as long as they are active (and needed) is clearly beneficial.

Materials and Methods

Protein expression and purification. His-tagged BtuC₂D₂ and FLAG-tagged BtuF were over-expressed and purified as was extensively described before^{17,54}. Briefly, BtuC₂D₂ was overexpressed from single plasmid containing an amino terminal histidine tag on BtuC. Cells lysate was solubilized in 1% dodecyl-N,N-dimethylamine-oxide (LDAO, Affymetrix) and BtuC₂D₂ was purified using Ni-NTA metal affinity chromatography. FLAG-tagged BtuF was purified from osmotic shock extracts by size exclusion chromatography.

Incubation regimes. 50–100 µg BtuC₂D₂ (1 mg/mL) were dialyzed in the dark at the indicated temperatures against a 1000-fold excess of buffer containing 25 mM Tris-HCl, pH 7.5, 150 mM NaCl, 50 µM EDTA, 0.08% (w/v) N-dimethylamine-N-oxide (LDAO, Affymetrix), 0.008 mg/mL *E. coli* lipids. LDAO and *E. coli* lipids were omitted from experiments done in nanodiscs 100 µM ATP and 1 mM MgCl₂ were added to set the working regime, and ATP was omitted for the resting condition. To ensure a fresh supply of ATP the buffer was changed every 12–20 hours. The following conditions were used to mimic the intermediate bound states: ATP-bound: 100 µM Adenosine 5'-(β,γ-imido) triphosphate (AMP-PNP, Sigma)/ 1 mM MgCl₂ or 100 µM ATP/50 µM EDTA. Others and we have previously observed that both conditions mimic the ATP bound state^{28,31,50}. ADP bound: 100 µM ADP/1 mM MgCl₂. The transition state was trapped as previously described²⁸ using 300 µM ortho-vanadate in the presence of 100 µM ADP/ 1 mM MgCl₂. Samples were withdrawn at the indicated time points and centrifuged before analysis (10 minutes 17,000 x g, or 30 minutes 150,000 x g as indicated).

ATP hydrolysis assays. The hydrolysis of ATP, GTP, or CTP was measured using Molecular Probes (USA) EnzCheck[®] kit, at 28 °C in a 96-well format, according to the manufacturer's specifications and as described in⁵⁵. Each well contained 100 µL of 0.1–1 µM BtuC₂D₂ (as indicated) in 25 mM Tris-HCl, pH 7.5, 150 mM NaCl, 50 µM EDTA, 0.008 mg/mL *E. coli* lipids, and 0.08% (w/v) N-dimethylamine-N-oxide (LDAO, Affymetrix). LDAO was omitted from experiments with reconstituted nanodiscs and liposomes. To initiate hydrolysis, MgCl₂ was injected to a final concentration of 2 mM (or 1 mM in assays with liposomes).

SPR measurements. The procedure for measuring the interaction between BtuC₂D₂ and BtuF using SPR had been extensively described^{28,29}. Briefly, BtuC₂D₂ (15–20 ng, 1500–2000 RU) was immobilized onto a Ni-NTA biosensor chip (GE healthcare) and FLAG-tagged BtuF was injected at the indicated concentration. All measurements were conducted on using a Biacore[™] T200 (GE healthcare), at 25 °C, and the block compartment was cooled to 7 °C. Experiments were run in 50 mM Tris-HCl pH 7.5, 150 mM NaCl, 0.1% (w/w) n-dodecyl-N, N-dimethylamine-N-oxide (LDAO) at 15 µL min⁻¹ (mass transport limitations were not observed). Where appropriate, ligands (vitamin B₁₂, nucleotides) were added only to the analyte's buffer (BtuF). Double referencing was applied to all sensograms.

Reconstitution of BtuC₂D₂. BtuC₂D₂ was reconstituted essentially as previously described¹⁷ with minor modifications. Egg phosphatidylcholine and *E. coli* polar lipids (Avanti) were mixed in chloroform in a 1:3 ratio (w/w). Chloroform was removed under a gentle nitrogen stream and residual chloroform was removed by over-night vacuum. The lipids were re-suspended in nitrogen-flushed 20 mM Tris-HCl pH 7.5 at 10 mg/mL by vortexing and sonication in a bath sonicator. Lipids (10 mg/mL) were stored at –80 °C until use. For reconstitution, lipids were thawed in a room temperature water bath, subjected to three rounds of freezing (liquid nitrogen) and thawing (water bath), and extruded 11 times through a double layer of 400 nm polycarbonate filters (using Avanti Polar Lipids Mini-Extruder). Purified BtuC₂D₂ (1 mg/mL in 0.1% LDAO) was then added at a 1:50 ratio (w/w) of protein/lipids and the mixture was gently agitated for 30 minutes at room temperature. BioBeads SM2 (BioRad) were used to remove the detergent. Before their use, the BioBeads were activated by washing (once) with methanol, three times with ethanol, and five times with water. BioBeads were added at 40 mg/mL for 15 minutes at room temperature, 15 minutes at 4 °C, 30 min at 4 °C, overnight at 4 °C, and finally 1 hour at 4 °C. Fresh beads were used for in each exchange. The proteoliposomes were harvested by ultracentrifugation (20 minutes, 150,000 x g), washed with nitrogen-flushed 20 mM Tris-HCl pH 7.5, re-suspended in the same buffer to 10 mg/mL, frozen in liquid nitrogen and stored in –80 °C.

Rapid reconstitution of BtuC₂D₂. The protocol used for reconstituting primed BtuC₂D₂ (shown in Fig. 4C) is similar to the one described above with the some modifications. Prior to reconstitution of pre-conditioned BtuC₂D₂ the liposomes were loaded with an ATP regenerating system (see below). Subsequently, all steps were carried in 4 °C, and following a 20-minute incubation of primed BtuC₂D₂ with the pre-formed, pre-loaded liposomes the detergent was immediately removed by 4 successive incubations with 160 mg/mL SM-2 bio beads, each incubation for 15 minutes. The proteoliposomes were then diluted 3-fold with detergent free buffer, collected by ultracentrifugation (15 minutes, 150,000 x g) rinsed once (without re-suspension) with 1 ml of 20 mM Tris-HCl pH 7.5, 150 mM NaCl, 2 mM MgCl₂, and re-suspended to 10 mg/mL. For transport assays with reconstituted pre-conditioned BtuC₂D₂ the proteoliposomes were immediately used for transport assays, without freezing.

Sucrose floatation assays. To remove proteins that are not membrane embedded, 50 µl of proteoliposomes used in the transport assays were washed with 100 mM Na₂CO₃, 20 mM Tris-HCl pH 7.5, 150 mM NaCl. Proteoliposomes were then placed at the bottom of ultracentrifugation tube and density cushions of 60, 40, and 0% (w/v) sucrose were built on top (volumes of 0.95 ml, 2 ml, and 1 ml respectively). Samples were centrifuged (50,000 X g, 4 °C, 16 hours) using ultracentrifuge in swinging rotor (SW TH660). Ten fractions of 0.4 ml each were gently collected and analyzed by western blot using anti His antibody.

Transport assays in proteoliposomes. Uptake of vitamin B₁₂ was measured using previously established protocol¹⁷ with several modifications. To incorporate an ATP regenerating system the proteoliposomes suspension was supplemented with 1 mM Na-ATP, 2 mM MgCl₂, 20 mM creatine phosphate, and 0.06 mg/mL creatine kinase. The proteoliposomes were then subjected to three cycles of freeze/thaw and extruded 11 times through a double layer of 400 nm polycarbonate filters. Following one wash with 20 mM Tris-HCl pH 7.5, 150 mM NaCl, 2 mM MgCl₂, the proteoliposomes were re-suspended with the same buffer to 10 mg/mL lipids. All steps were preformed in 4°C and the proteoliposomes were kept on ice. To initiate transport, the proteoliposomes were diluted to 5 mg/mL, heated to 33°C for 2 minutes, and combined with 0.5 μM BtuF/5 μM ⁵⁷Co-labeled vitamin B₁₂ (MP biomed, 1.67 μCi/mL). At the indicated intervals a 50 μL sample was removed, diluted with 4 ml of ice-cold 20 mM Tris-HCl pH 7.5, 150 mM NaCl, 2 mM MgCl₂, 100 μM unlabeled vitamin B₁₂, and immediately filtered through 0.2 μM cellulose acetate filters. The filters were washed once with 4 ml of the same ice-cold buffer. The amount of ⁵⁷Co-labeled vitamin B₁₂ on the filters was determined using a γ counter.

Nanodisc reconstitution. The method for self-assembly of membrane protein in monodisperse phospholipid bilayer, held by a scaffold protein was established in³⁰ and used for ABC transporters. Nanodiscs containing BtuC₂D₂ were prepared using tag-less membrane scaffold protein (MSP1-E3D1) and lipids as describe in³¹. Briefly, purified BtuC₂D₂ complex in LDAO was mixed with purified, TEV cleaved MSP1-E3D1 and lipids (*E. coli* polar lipids and phosphatidylcholine at a 3:1(w/w) ratio, and solubilized in 4% Triton X-100) to final concentrations of 4 μM, 24 μM and 0.85 mM respectively. After a 30-min incubation under gentle agitation at room temperature, detergents were removed by BioBeads, with 250 mg BioBeads per 1 ml mixture, 15 min at room temperature followed by 3 incubations of 15, 30, and 120 minutes at 4°C (fresh beads were used each time).

Tryptophan fluorescence measurements. Nucleotides were removed from the protein samples with Zeba™ Spin Desalting columns, 40 K MWCO (Thermo Scientific) and the samples were diluted to 0.2 mg/mL with the dialysis buffer (excluding the nucleotides). Triplicates of 50 μL were excitation-scanned (Ex 230–440 nm, Em 330 nm) using a monochromator-based Tecan M200 plate reader.
