In Nature, protons (H^+) can mediate metabolic process through enzymatic reactions. Examples include glucose oxidation with glucose dehydrogenase to regulate blood glucose level, alcohol dissolution into carboxylic acid through alcohol dehydrogenase, and voltage-regulated H^+ channels activating bioluminescence in firefly and jellyfish. Artificial devices that control H^+ currents and H^+ concentration (pH) are able to actively influence biochemical processes. Here, we demonstrate a biotransducer that monitors and actively regulates pH-responsive enzymatic reactions by monitoring and controlling the flow of H^+ between PdH_x contacts and solution. The present transducer records bistable pH modulation from an “enzymatic flip-flop” circuit that comprises glucose dehydrogenase and alcohol dehydrogenase. The transducer also controls bioluminescence from firefly luciferase by affecting solution pH.

In nature, H^+ plays an important role in modulating enzymatic reactions during metabolic process to fulfill physiological functions^{1,2}. Examples include glucose oxidation with glucose dehydrogenase to maintain the blood glucose level, alcohol digestion into carboxylic acid through alcohol dehydrogenase, and voltage-regulated H^+ channels activating bioluminescence in firefly and jellyfish³. There are several bioelectronics devices that use enzymatic reactions to regulate device output such as biofuel cells⁴, organic electrochemical transistors biosensors⁵, and enzyme logics mimicking electronic circuits⁶. In turn, bioelectronic devices may regulate electron mediated enzymatic reactions^{7,8}. However, not all enzymatic reactions are electron mediated and control of enzymatic reactions with devices^{9–12} that modulate ionic currents is desirable.

Examples of these devices include ion pumps based on conducting polymers that can deliver Ca^{2+} and the positive charged neurotransmitter gamma-aminobutyric to brain tissues for potential treatment of epilepsy¹³, metallic nanostraws¹⁴ and carbon nanotube porins that^{15,16} deliver selectively target molecules such as cations¹⁵, DNA¹⁴, and nicotine¹⁶. H^+ also plays important roles in modulating physiological function¹⁷. We have developed bioprotonic devices that selectively control the flow of H^+ including complementary field effect transistors^{18,19}, synaptic memories²⁰, and enzyme logic⁶. Recently, H^+ transistors with the protein reflectin have been demonstrated²¹. These bioprotonic devices are based on PdH_x as a transducer between H^+ currents in the device or solution and e^- current in the electronic circuit. Here, we develop an electrochemically-controlled PdH_x biotransducer that not only records but also modulates the pH of a solution. We integrate this biotransducer with enzymatic reactions to implement H^+ mediated monitoring and control of biochemical processes (Fig. 1). The biotransducer converts the input of an enzymatic flip-flop circuit – a bistable circuit with a high pH and a low pH state controlled by the enzymes glucose dehydrogenase and alcohol dehydrogenase – to a readable H^+ current as the output (Fig. 1a), and it provides pH modulation as the input for the pH sensitive enzymatic reaction of luciferin and luciferase with bioluminescence as the output (Fig. 1b).

Results

PdH_x protodes measure the pH of a solution because the transfer of H^+ between PdH_x and the solution is affected by the difference in chemical potential of H^+ , or protochemical potential (μ), between the PdH (μ_{PdH}) and the solution (μ_{pH}) (Fig. S1)^{6,22}. This difference is defined as²²

Figure 1. H^+ mediated enzymatic reactions. (a) Schematic of the enzymatic flip flop circuit as a bistable pH modulating system controlled by logically processed biochemical signals. The ‘set’ operation is the glucose input. The reaction between glucose and the enzyme glucose dehydrogenase (GDH) increases H^+ concentration in solution and lowers the pH. Acetaldehyde (Act) reacts with the alcohol dehydrogenase (ALD) enzyme. The reaction consumes H^+ in the reaction and increases the pH. The GDH and ALD AND enzyme logics regulate the solution pH, thus affect H^+ transfer between solution and the contact. H^+ combines with an electron at the Pd contact and forms PdH. The PdH biotransducer converts the biochemical signals into readable protonic current. (b) Schematic of firefly bioluminescence reaction integrated with pH modulating biotransducer. Luciferin is oxidized into oxy-luciferin with the presence of the luciferase enzyme. The reaction emits light. The solution pH affects the color of the light emitted. When the PdH pH modulator transfers H^+ between the solution and the contact, it changes the solution pH. The bioluminescence light is the solution pH change readout.

$$\mu_{\text{PdH}} - \mu_{\text{pH}} = eV + k_B T \ln(a_{H^+}/(p_{H_2})^{1/2}) \quad (1)$$

where a_{H^+} = activity of H^+ in solution with $pH = -\log a_{H^+}$, p_{H_2} = hydrogen partial pressure in the Pd V = potential difference between Pd and solution

According to $\text{PdH} \leftrightarrow \text{Pd} + H^+ + e^-$, the H^+ transfer results in a measurable electronic current. In our previous work, we have demonstrated recording of the pH readout of an enzymatic AND gate comprising glucose (Glc) and NAD^+ with glucose dehydrogenase (GDH)¹⁵. In the presence of both NAD^+ and Glc, GDH lowers the solution pH, which is recorded with the PdH_x protodes. In the absence of either substrate, GDH is not active and the solution pH remains the same²³. GDH modifies the pH only once because the enzymatic AND gate does not include a feedback loop to make the reaction reversible and return the solution to its original pH. Here, we integrate the enzyme alcohol dehydrogenase (ALD) with GDH to create an enzymatic flip-flop with a bistable pH modulation as the read out (Fig. 1a). A flip-flop is a circuit made by two AND gates. The output of the first AND gate is fed back as one of the inputs of the second AND gate and vice versa. In this fashion, a flip-flop has two stable states and can be used to store information. A set and a reset inputs switch the flip-flop between the two states. The enzymatic flip-flop consists of two types of enzymatic AND logic that use GDH and ALD as gates. GDH requires the presence of both NAD^+ and Glc as inputs to function. GDH produces NADH and gluconic acid (GlcA), which lowers the solution pH from 6.0 to 4.3 (Fig. S2a). NADH, the output of the GDH, is one of the inputs for ALD with acetaldehyde (Act) as the other input. In the presence of both NADH and Act, ALD produces ethanol and NAD^+ . NAD^+ , in turn, is the input of the GDH logic gate. ALD consumes H^+ during this enzymatic reaction and induces an increase in solution pH from 7 to 9.7 (Fig. S2b). The products (NADH or NAD^+) of each AND gate (ALD or GDH) are connected to one of the inputs of the other gate. This connection results in a positive feedback that creates an enzymatic flip-flop²⁴. The life-time of the flip-flop circuit depends on the life-time of the bistable pH modulation and the devices are functional for at least one day when stored at low temperature. In our system, the ‘set’ operation is Glc injection, which causes a decrease in pH and an associated increase in the solution μ_{pH} . The reset operation is Act injection, which causes an increase in pH and an associated decrease in the solution μ_{pH} . Solution pH is used as the readout.

To read out the state of the enzymatic flip-flop, we integrate it with the PdH_x electrochemical biotransducer and monitor the transfer of H^+ between the solution and the PdH_x protode at a given applied voltage as function of the pH state (Fig. 2a) (Fig. S1). To this end, we use a standard three-electrode configuration with Pd (PdH_x) as the working electrode (WE), Ag/AgCl as the reference electrode (RE), and platinum (Pt) as the counter electrode (CE). In this setup, a large enough cathodic voltage, V_c , applied to the WE (negative vs. Ag/AgCl) transfers an H^+ from the solution to the Pd where H^+ combines with an e^- to form H. H adsorbs onto Pd to form PdH_x . In general, H adsorption into the Pd nanofilm can expand its volume up to 10% after forming the PdH_x ²⁵, so the film thickness (50 nm Pd) will increase up to 55 nm of PdH . We monitor this H^+ transfer by recording the cathodic current, I_c , resulting from the e^- that flow into the Pd WE and participate in the reduction of H^+ to H. A large enough reverse anodic voltage, V_a , applied to the WE (positive vs. Ag/AgCl) causes an H^+ to transfer from the PdH_x to the solution leaving an e^- behind, which leads to an anodic current I_a (electron flowing out of the Pd

Figure 2. The biotransducer transduces the set-reset enzymatic flip-flop signals into current. (a) Enzymatic flip-flop integrated with the PdH biotransducer. The electrochemical setup has a Pd working electrode, Ag/AgCl reference electrode and Pt counter electrode. V_a and V_c is applied to Pd vs. Ag/AgCl. I_a and I_c is measured between Pd and Pt. The reaction between glucose and NAD^+ , catalyzed by the enzyme GDH, produces gluconic acid (GlcA) and NADH. Acetaldehyde (Act) reacts with the ALD enzyme and produces ethanol and NAD^+ . (b) Upper panel shows the pH change when adding Glc and Act into the solution. Lower panel shows I_c and I_a in response to pH change. $V_c = 0$ V and $V_a = -0.95$ V is applied during the ‘set’ and ‘reset’ process respectively. I_c is recorded during $V_c = 0$ V, and I_a is recorded during $V_a = -0.95$ V. I_a is almost 0 when solution is above pH 6. At $V_a = -0.95$ V, few H^+ can be transferred into Pd contact. pH 5.5 induced by the addition of Glc into the solution causes $I_a = 0.16$ mA. The return of pH to above 6 with the addition of Act results in no I_a . (c) Truth table of the set-reset enzymatic flip-flop circuit.

WE). When all of the PdH_x is transformed into Pd, I_a goes to zero. The magnitude of I_a is proportional to the extent of PdH_x formation in the cathodic phase because it is directly correlated to how many H^+ have previously transferred from the solution into the PdH_x ²⁶. We use the magnitude of I_a as an indirect means of monitoring H^+ transfer from solution into the PdH_x because I_c also contains components related to charging of the solution.

In the initial state of the flip-flop, the solution pH = 7.5 and $V_c = -0.95$ V. According to the process map (Fig. S1) H^+ do not transfer from the solution to the Pd contact, $I_c = 0$ A, and setting $V_a = 0$ V results in $I_a = 0$ A because PdH_x did not form when V_c was applied (Fig. 2b). We keep $V_c = -0.95$ V during the ‘set’ operation when we add Glc (Fig. 2b). Adding 3 mM Glc to the solution causes the pH to drop from 7.5 to 5.5. Now, with $V_c = -0.95$ V,

Figure 3. pH regulation in solution. (a) Schematics of pH modulator with CNT modified CF counter electrode. In (a), with Pd contact there is no I_a at $V_a = 0.9$ V. At $V_c = -0.9$ V, H^+ transfers from solution into the Pd and recombines with e^- to form H. H adsorbs onto Pd and forms PdH . Decrease of H^+ concentration in solution causes pH increase in solution. (b) Pictures of pH modulator with pH paper in solution. Yellow color of the paper indicates pH = 7.0 in solution, which is the initial pH of solution. Dark blue color indicates pH = 10.0 in solution. pH increase is due to H^+ transfer from solution to Pd contact.

H^+ transfer from the solution to the Pd contact and form PdH_x . For PdH_x , μ_{PdH} is higher than μ_{pH} when the pH = 5.5. When we switch to $V_a = 0$ V, H^+ transfer back to the solution. The I_a resulting from this transfer is as high as 0.16 mA. The 'reset' operation of adding Act in the presence of NADH engages the ALD enzymatic reaction, which consumes H^+ and brings the pH back close to neutral with a value of pH = 6.5. At pH = 6.5, H^+ do not transfer into the Pd when $V_c = -0.95$ V and PdH_x does not form. As a result, when V_a is set to 0 V, $I_a = 0$ mA.

Using these inputs and readouts, we produce a truth table for the enzymatic flip-flop (Fig. 2c). The output, or memory readout, switches between two states defined digitally as 0 (neutral pH) and 1 (low pH). These two states correspond to either $I_a = 0$ mA or $I_a \gg 0$ mA. The enzymatic flip-flop is activated by 'set' and 'reset' input signals applied at two levels digitally defined as 0 and 1. The presence of the 'set' Glc or the 'reset' Act is digital 1 and their absence is digital 0. Application of 'set' = 0 and 'reset' = 0 preserve the readout state regardless of its original value (0 or 1). Application of 'set' = 1 results in the readout state 1, while application of 'reset' = 1 yields the readout state 0, regardless of the original readout state (0 or 1). As in a digital flip-flop, the simultaneous application of the signals 'set' = 1 and 'reset' = 1 sends the system in opposite directions, results in an unstable readout, and it is not permitted. The enzymatic flip-flop demonstrates how the Pd/PdH_x biotransducer transduces H^+ signals in the form of pH change from the enzymatic readouts into measurable electronic currents.

In addition to the protonic readout from an enzyme logic signal, we use this PdH_x biotransducer to modulate pH in solution (Fig. 3a). When V_c is applied to the WE and H^+ transfer from solution into the Pd contact, the net concentration of H^+ in solution decreases and the pH increases (Fig. 3a). At the same time, when V_a is applied to the WE and H^+ transfer from the PdH_x contact into the solution, the net concentration of H^+ in the solution increases, and the pH decreases (Fig. 3a). Since the voltage applied to the WE, V_c or V_a , controls whether H^+ flow from the solution into the PdH_x contacts and vice versa, the net result is electronic pH control. In order to achieve this electronic pH control, we keep the conventional three-electrode system used in enzymatic flip-flop setup. This setup, however, does not produce the desired results because of the high catalytic property of the Pt CE. It is likely that redox reactions ($4H^+ + O_2 + 4e^- \rightarrow 2H_2O$; $2H^+ + 2e^- \rightarrow H_2$; $2H_2O + 4e^- \rightarrow H_2 + 2OH^-$) on the CE consume the H^+ injected from the WE with no change in solution pH. To overcome this issue, we use a counter electrode that is inert and with high capacitance, similar to the electrodes used in electrochemical double layer capacitors²⁷. We use a high capacitive carbon fabric decorated with carbon nanotube (CF/CNT), with a capacitance per unit area $C_i = 6.5$ mF/cm²²⁸. We first attempt to increase the pH of a Na_2SO_4 solution with initial pH = 6.8 (Fig. 3b). With $V_c = -0.9$ V on the WE, H^+ transfer from the solution into the WE and form PdH_x . The H^+ concentration in the solution decreases and the pH increases as indicated by the pH paper changing color from yellow (neutral pH) to dark blue (basic pH) (Fig. 3b). The Pd WE also changes color from metallic silver into a darker gray as expected from the transformation of Pd into PdH_x , as we have previously observed²⁰. As a control, we confirm that with an Au WE the pH change is much smaller than when using the PdH_x WE (Fig. S3). This is because the Au WE is not able to directly inject or sink H^+ at the solution interface. The small pH change that we still observe with the Au WE may be due to H^+ or OH^- accumulating at the Au charged surface or other surface catalytic reactions²⁹. However, the pH change with Pd protode is much higher than that with Au WE because the Au does not promote H^+ transfer between the WE and the solution. When $V_a = 0.9$ V is applied to the PdH_x WE, PdH_x injects H^+ back into the solution, which returns to its original pH (Fig. S4). This pH modulation

Figure 4. Bioluminescence incorporated with pH modulating biotransducer. (a) Schematic of the pH modulator integrated with bioluminescence enzymatic reaction. Change of pH lights up the solution due to the optimal pH of the enzyme reaction is reached. (b) The firefly bioluminescence at different solution pH. At acidic pH 6, solution shows red color. At neutral to basic pH, solution is yellow. The optimal pH of firefly luciferin luciferase reaction is pH 8, thus strongest light emission. (c) Bioluminescence turned on and off by the pH modulator. The initial pH of solution is 5.8. When applied $V_c = -0.9$ V, pH increases to reach the optimal pH for the enzymatic reaction. Bioluminescence turns on. When reversed to $V_a = 0.9$ V, solution pH returns to initial pH and bioluminescence is off. Bioluminescence can be turned on and off for several cycles.

is reversible and solution pH cycles between pH = 6.8 to pH = 9.2 several times (Fig. S5). While the inert CF/CNT enables pH modulation of solution by minimizing side reactions at the CE, likely some of these reactions remain and optimization of the system is required to increase the range of pH modulation.

We demonstrate pH control in solution with an optical output by modulating the output bioluminescent enzymatic reactions (Figs 1b and 4)³⁰. We choose to modulate the yellow-green glow that in nature is emitted by the firefly. This glow is a result of the oxidation reaction of firefly luciferin, catalyzed by the enzyme luciferase in the presence of ATP as the energy source (Fig. 1b). This enzymatic reaction is pH sensitive³⁰. To this end, we utilize a Japanese toy (Photolight), which contains one packet of firefly luciferase, and the other packet of its substrate luciferin, ATP powder, and Mg^{2+} , which is consumed during the reaction. We test the reaction at different pH and obtain the highest output at pH = 8 (Fig. 4a). The color also changes as a function of pH from yellow to bright green and ultimately to red when the solution pH changes from basic to acidic (Fig. 4a). This color change is consistent with prior reports³¹. We place the solution at pH = 6.7 containing the Photolight components in a PDMS chamber that includes the electrode setup used previously (Fig. 4b). When $V_c = -0.9$ V at the WE, H^+ transfer from the solution to the Pd/PdH_x WE and result in an increase of solution pH. When pH = 8 is reached in the solution, the bioluminescent output increases with a bright yellow color (Fig. 4c). When $V_a = 0$ V at the WE, H^+ transfer back into the solution, which returns to its original pH turning the bioluminescence off. This pH controlled bioluminescence can be cycled between the low pH off state and the high pH on state. We have not thoroughly mapped performance and lifetime for this process. In preliminary measurements we were able to turn the bioluminescence ON and OFF for at least four cycles. (Fig. S6).

To decrease solution pH in addition to increase solution pH, we develop a pH modulator circuit with two Pd/PdH_x WE and two separate chambers (Fig. 5a). The two chambers and Pd/PdH_x WE act as H^+ reservoirs for each other. The two WE are connected by a strip of proton conducting polymer (Nafion), which transfers H^+ between the two Pd/PdH_x contacts when a transfer voltage (V_T) is applied²⁰. Again, to monitor pH change in the two chambers we use firefly bioluminescence (Fig. 5b). We start with the chamber of the right at pH 6.5 and the chamber on the left at pH 7.5 as indicated by a reddish (right) and bright yellow (left) bioluminescent output. We start with the chamber on the right slightly acidic to ensure that there are enough H^+ to transfer into the Pd WE. First, we apply $V_c = -0.9$ V to the Pd WE on the right and load it with H^+ from the solution. Solution pH in the right chamber increases as indicated by the bioluminescent output color change from red to yellow. Second, we apply a transfer voltage $V_T = 1.2$ V between the two Pd WE to transfer the H^+ from the right WE to the left WE along the Nafion H^+ conducting bridge. At this stage, $V_c = 0$ V and it is likely that some of the H^+ from the PdH move back to the solution with higher pH and lower protochemical potential⁶. This transfer results in the pH in the right chamber returning to slightly acidic. Third, we apply $V_a = 0.6$ V to the WE on the right and transfer the H^+ from the WE to the solution in the left chamber. The pH in the left chamber decreases as indicated by a change

Figure 5. Bioluminescence incorporated with pH modulator circuit. (a) Schematic of the pH modulator circuit integrated with bioluminescence enzymatic reaction, (b) PDMS chamber contains firefly bioluminescent enzyme that changes color as function of solution pH.

in color from bright yellow to red. If we apply $V_a = 0.6$ V to the left chamber without previously transferring H^+ from the right chamber and right WE, we do not observe any noticeable pH change.

Discussion and Conclusions

We demonstrate a Pd/PdH_x based protonic biotransducer that records and modulates pH dependent enzymatic reactions. This recording and modulation is based on the pH dependence of the transfer of H^+ between solution and Pd/PdH_x. By coupling this biotransducer with two enzymatic AND gates, we demonstrate an enzymatic flip-flop that sets a high and a low pH state. Such integrated logic system may allow for future implantable bio-medical devices controlled by physiological conditions. Further, we provide an optical output for pH modulation by using firefly bioluminescence with pH dependent color and intensity. While we modulate the pH of the entire solution, it is likely that the pH at the surface of the PdH_x contacts is different due to expected electrostatic charging effects. We are able to modulate the solution pH between 6.8 and 9.6 with an increase in efficiency required to access a broader pH spectrum. This broader pH spectrum is required for controlling biological function in solutions with high buffering capacity such as physiological conditions²⁶.

Materials and Methods

Devices are fabricated on microscope glass slide (2.5 cm × 4.5 cm VWR). 50 nm Pd with a 15 nm Cr adhesion layer is deposited via e-beam evaporation (Balzers PLS 500). PDMS wells (made from 5 mL PDMS solution) are used as solution containers and attached to the Pd substrates with PDMS. For the pH modulator circuit, 3.5 wt% agarose gel solution is used to seal between the PDMS wells and the substrates. Fully hydrated agarose gel is placed above the Nafion channel to hydrate the material. After 15 min we assume that the Nafion is fully hydrated and we begin the measurement. 200 μ L Nafion 117 solution (5% concentration) from Sigma Aldrich is drop-cast on top of the patterned Pd substrate and the solution is dried in a fume hood. Glucose dehydrogenase (EC 1.1.47) is donated from TOYOBO enzymes. Alcohol dehydrogenase (EC 1.1.1.1), glucose, acetaldehyde, nicotinamide adenine dinucleotide, Na₂SO₄, MgSO₄, universal pH indicator are purchased from Sigma Aldrich. Luciferin and luciferase are from the Photolight (Japan). Carbon fiber (TCC-3250) is donated from Toho Tenax Co. Carboxylic groups modified carbon nanotubes (20–30 nm) are purchased from Cheap Tubes.com. The CNT modified CF electrode follows a previously reported method²⁸. Electrochemical measurements are performed with a potentiostat (BAS, model2325).

This work was supported by the National Science Foundation under CAREER Award DMR-1150630 (enzymatic flip-flop and bioluminescence) and U.S. Department of Energy (DOE), Office of Science, Basic Energy Sciences (BES), under Award No. <DE-SC0010441> (H⁺ transfer between Pd/PdH_x and solution). T.M. acknowledges a fellowship from the Japan Society for the Promotion of Science. Part of this work was conducted at the Washington Nanofabrication Facility/Molecular Analysis Facility, a member of the NSF National Nanotechnology Infrastructure Network.

Author Contributions

Y.D. and T.M. designed the experiment. Y.D., S.K. and T.M. performed the experiment. E.J. fabricated the device. Y.D., S.K. and T.M. analyzed the data. Y.D., T.M. and M.R. wrote the manuscript. All the authors revised the manuscript.
