High salt intake is a major risk factor for hypertension. Although acute caffeine intake produces moderate diuresis and natriuresis, caffeine increases the blood pressure (BP) through activating sympathetic activity. However, the long-term effects of caffeine on urinary sodium excretion and blood pressure are rarely investigated. Here, we investigated whether chronic caffeine administration antagonizes salt sensitive hypertension by promoting urinary sodium excretion. Dahl salt-sensitive (Dahl-S) rats were fed with high salt diet with or without 0.1% caffeine in drinking water for 15 days. The BP, heart rate and locomotor activity of rats was analyzed and urinary sodium excretion was determined. The renal epithelial Na⁺ channel (ENaC) expression and function were measured by *in vivo* and *in vitro* experiments. Chronic consumption of caffeine attenuates hypertension induced by high salt without affecting sympathetic nerve activity in Dahl-S rats. The renal α -ENaC expression and ENaC activity of rats decreased after chronic caffeine administration. Caffeine increased phosphorylation of AMPK and decrease α -ENaC expression in cortical collecting duct cells. Inhibiting AMPK abolished the effect of caffeine on α -ENaC. Chronic caffeine intake prevented the development of salt-sensitive hypertension through promoting urinary sodium excretion, which was associated with activation of renal AMPK and inhibition of renal tubular ENaC.

High salt intake is a major risk factor of hypertension^{1,2}. Epidemiological studies demonstrate that more than 60% of hypertensive individuals are salt-sensitive³. Although reducing daily salt intake 2.0 to 2.3 grams can decrease deleterious cardiovascular events by 20%⁴, it is difficult to achieve this goal by health education. A survey showed that there was no significant reduction in salt intake in the US over the past 20 years⁵, and only a few countries meet the daily salt intake level of 6 g/day recommended by WHO⁵. Currently, several diuretic and natriuretic drugs are commonly used to promote the urinary sodium excretion in hypertensive patients⁶. Thus, it is crucial to find a more acceptable approach for promoting urinary excretion in normal or pre-hypertensive population.

Caffeine (1, 3, 7-trimethylxanthine) is the most commonly used psychoactive agent consumed daily by nearly 80% of the world's population and 90% of adults in North America in forms of coffee, tea and food^{7,8}. Caffeine was used historically to increase urine output before its more potent pharmacological diuretics became widely available⁹. Although acute effect of caffeine increases blood pressure and heart rate^{10,11}, chronic caffeine administration prevents diet-induced insulin resistance^{12,13}, attenuates metabolic syndrome through weight loss and reduction in fat mass¹⁴ as well as reduces fructose-induced hypertension¹⁵.

It is well documented that impaired renal sodium excretion plays a critical role in the pathogenesis of hypertension^{16,17}. The thiazide-sensitive NaCl cotransporter (NCC), amiloride-sensitive epithelial sodium channel

(ENaC), and sodium hydrogen (Na/H) exchanger are major regulators of renal tubular sodium reabsorption and of blood pressure^{18,19}. Among them, ENaC mediates apical entry of sodium in the aldosterone-sensitive distal tubule and collecting duct and accounts for the rate-limiting step for sodium reabsorption in these nephron segments²⁰. ENaC activity is stimulated by kinases such as SGK1 and PKA and inhibited by PKC, ERK1/2 and AMPK²¹. Caffeine can activate AMPK in different type of cells, including the vascular endothelial cells, skeletal muscle cells and hepatocytes^{22–24}. However, it is unknown whether caffeine regulates ENaC function in distal nephron through AMPK or other kinases.

In the present study, we hypothesized that long-term caffeine consumption inhibits ENaC function in distal nephron, which in turn increases urinary sodium excretion and prevents hypertension induced by high salt intake. To test this hypothesis, the Dahl's salt sensitive rat, a salt-sensitive hypertension model^{25,26}, was examined in this study. We provide *in vivo* and *in vitro* evidence that AMPK activation by caffeine promoted urinary sodium excretion and lowered blood pressure through inhibition of the ENaC function in salt-sensitive rats. The present results also suggest that the acute and chronic actions of caffeine are mediated via different sites of the kidney tubules.

Results

Effect of chronic caffeine intake on blood pressure. Despite lower water and food intake in the first three days, chronic caffeine intake had no effect on water and food intake in Dahl-S rats thereafter (Fig. 1a,b), but significantly decreased their body weight compared with controls from the 12th day of treatment (Fig. 1c). Similarly, although caffeine intake temporally increased blood pressure on the second day, long-term caffeine intake attenuated high salt-induced increase in systolic, but not diastolic blood pressure in a time dependent manner (Fig. 1d,e). Also, 24-hr ambulatory systolic blood pressure on the 15th day was lower in caffeine-treated rats. This anti-hypertensive effect of chronic caffeine was more obvious at night when the rats were more active (Fig. 1f). 24 hr ambulatory diastolic blood pressure did not differ between the two groups (Fig. 1g).

Effect of chronic caffeine intake on sympathetic nerve activity and vascular function. On the second day, caffeine initially increased heart rate and locomotor activity, after that, there were no significant difference in heart rate and locomotor activity between control and caffeine-treated Dahl-S rats (Fig. 2a,b). Accordingly, the plasma catecholamine concentration was not different between the two groups (Fig. 2c). In addition to sympathetic nerve activity, electrical field stimulation (EFS)-induced mesenteric artery constriction was not affected by caffeine (Fig. 2d). Similarly, both of endothelium-dependent and independent relaxations of mesenteric arteries were almost equal between the two groups (Fig. 2e,f). These results indicate that neither sympathetic nerve activity nor vascular function is responsible for the anti-hypertensive effect of chronic caffeine intake.

Chronic caffeine intake increases urinary sodium excretion. To investigate whether chronic caffeine intake has a diuretic or natriuretic effect, we measured the 24-hr urinary volume and urinary sodium concentration of caffeine-treated rats and control rats. Interestingly, despite not altering 24-hr urinary volume (Fig. 3a), chronic caffeine intake increased the urinary sodium concentration and sodium excretion (UNaV) (Fig. 3b,c) without affecting plasma sodium concentration (Fig. 3d). Therefore, increase of urinary sodium excretion would mainly contribute to the anti-hypertensive effect of caffeine.

Chronic caffeine intake inhibits renal α -ENaC. We further examined which renal sodium transporter involved in the effects of caffeine. Long-term administration of caffeine decreased the α -ENaC protein expression in cortical collecting duct of Dahl-S rats, whereas amounts of β - and γ -subunit proteins of ENaC were unchanged. The protein level of the thiazide-sensitive NaCl cotransporter (NCC) in the distal tubule was also unchanged by chronic caffeine intake (Fig. 4a and Supplementary Fig. 1). To establish the importance of ENaC in the effect of caffeine on urinary sodium excretion, Dahl-S rats were given an intraperitoneal injection of amiloride (3 mg/kg), a specific ENaC inhibitor. The ENaC-dependent sodium reabsorption was evaluated by the change in urinary sodium excretion after amiloride intervention. Caffeine-treated Dahl-S rats had a weaker ENaC-dependent sodium reabsorption than controls (Fig. 4b). In contrast, hydrochlorothiazide (12.5 mg/kg) inhibition of renal tubular transport of sodium by NCC was similar in control and caffeine-treated rats (Fig. 4c). Thus, the natriuretic effect of chronic caffeine intake was dependent on renal α -ENaC activity rather than NCC.

Caffeine treatment attenuates the ENaC function by activating AMPK. To investigate the mechanism underlying caffeine-induced increase in urinary sodium excretion mediated by α -ENaC inhibition, the expressions of kinase proteins were measured in cortical collecting duct cells (M1-CCD). Caffeine exposure for 24 hr decreased α -ENaC protein expression without affecting protein levels of SGK1, ERK1/2 and PKC α . An exception was α -AMPK and its phosphorylated form, which was increased in response to caffeine (Fig. 5a and Supplementary Fig. 2a). Thus we determined whether the effect of caffeine on α -ENaC subunit expression was dependent on AMPK. Caffeine exerted dose-dependent effects to increase α -AMPK and phosph-AMPK protein levels in association with reduced α -ENaC. Furthermore, compound C, an AMPK inhibitor, abolished the effects of caffeine on α -AMPK, phosph-AMPK and α -ENaC protein levels (Fig. 5b and Supplementary Fig. 2b). In addition, electrophysiological assessment of ENaC activity in M1-CCD cells demonstrated that caffeine exposure for 24 hr decreased the open probability of ENaC (Fig. 5c). These data indicate that caffeine treatment reduces protein levels of the α -ENaC by a mechanism involving AMPK and decreases the open-probability of ENaC in the renal collecting duct that leads to reduced sodium reabsorption and increased sodium excretion.

Discussion

The present study demonstrates that chronic caffeine administration promotes urinary sodium excretion and reduces blood pressure in salt sensitive hypertensive rats. Furthermore, this effect of caffeine is independent of the sympathetic nerve activation and vascular function. The natriuretic action of caffeine is mediated by inhibition of

Figure 2. Chronic caffeine intake has no significant impact on sympathetic nerve system and cardiovascular system. (a,b) Locomotor activity and heart rate changes in control and caffeine groups ($n = 5$). (c) Plasma catecholamine concentration on the 16th day ($n = 6$). (d) Electrical field stimulation-induced mesenteric arterial contraction is similar in control and caffeine groups. Results are expressed as a percentage of the initial contraction elicited by 60 mM KCl ($n = 5$). (e,f) Endothelium-dependent vasodilation induced by acetylcholine (ACh) was not significantly different in control and caffeine group ($n = 5$). Endothelium-independent vasodilation induced by nitroglycerin (NTG) was also similar in control and caffeine group ($n = 5$). Results are expressed as a percentage of the maximum contraction elicited by 10^{-5} M phenylephrine (PE). All data are presented as means $\pm$ SEM. * $P < 0.05$ compared with control.

renal α ENaC function without affecting the thiazide-sensitive NaCl cotransporter. In both *in vitro* and *in vivo* studies, caffeine up-regulated α AMPK level which suppressed α ENaC expression and activity.

Caffeine is a major ingredient in a number of the most widely consumed non-alcoholic beverages²⁷. Although the diuretic and natriuretic effects of caffeine have been recognized for long term, the mechanism responsible for caffeine effect was not fully elucidated. Thomsen *et al.* reported that acute caffeine intake increases lithium clearance that reflects sodium reabsorption in proximal tubule²⁸. Rieg *et al.* showed that the acute diuresis and natriuresis produced by caffeine were related to blockade of adenosine A_1 receptors²⁹. However, the chronic effects of caffeine on renal sodium handling are rarely investigated. The diuretic effect of caffeine is short-lived and is easy to develop tolerance³⁰. In addition, no dehydration was observed in habitual coffee drinkers³¹. These findings suggest that other mechanism might be involved when chronic caffeine use. In the present study, we found that

Figure 3. Chronic caffeine intake increases urinary sodium excretion without affecting plasma sodium concentration. (a) 24-hour urinary volume was not significantly different after high salt (control) or high salt plus caffeine (caffeine) intervention ($n = 5$) (b) Chronic caffeine intake increased urinary sodium concentration (c) Chronic caffeine intake increase 24-hour total urinary sodium excretion ($n = 5$). (d) Plasma sodium concentration analysis showed no difference in control and caffeine group ($n = 6$). All data are presented as means $\pm$ SEM. * $P < 0.05$, ** $P < 0.01$, compared with control.

chronic caffeine intake dominantly increased 24-hr urinary sodium excretion but not urinary volume in Dahl-S rats compared with control rats. This natriuretic effect but not diuretic effect suggested a primary action on renal sodium handling in chronic caffeine intake.

In our study, we showed that the urinary sodium excretion increased after caffeine intervention without change in plasma sodium concentration. Similarly, Burge *et al.* reported that long-term diuretics (amiloride and hydrochlorothiazide) administration at therapeutic dose have no influence on plasma sodium concentration³². Since caffeine displays a much weaker natriuretic effect than diuretics⁹, chronic caffeine administration would not affect plasma osmolality.

It is well documented that thiazide-sensitive NaCl cotransporter (NCC), amiloride-sensitive epithelial sodium channel (ENaC), and sodium hydrogen (Na/H) exchanger are major regulators of renal tubular sodium reabsorption thus affect blood pressure regulation^{18,19}. These epithelial sodium transporters can be regulated by several kinases such as protein kinase C, with-no-lysine kinase (WNK) 4 and 1, ERK 1/2, and serum- and glucocorticoid-inducible protein kinase 1 (SGK1), as well as AMPK^{16,21}. Disturbances of signaling via these kinase pathways can result in human sodium retention and hypertension^{33–36}. Previous studies in oocytes and epithelial tissues showed that AMPK inhibits sodium transport through increasing Nedd4-2-dependent ENaC retrieval from the membrane^{37,38}. Some studies reported that caffeine can activate AMPK in different type of cells^{22–24}. In the *in vivo* study, chronic caffeine intake decreased the protein levels and function of ENaC, but not NCC, which also affects renal electrolyte transport and blood pressure in the distal convoluted tubule³⁹. Thus, caffeine appears to increase urinary sodium excretion by inhibiting renal ENaC activity secondary to the AMPK pathway. However, whether caffeine inhibits the open probability of ENaC by regulating its expression or ability still needs further investigation.

We also confirmed that acute caffeine intake induced an initial increase in blood pressure in association with a transient increase in locomotor activity and heart rate in Dahl-S rats, which is likely associated with sympathetic nerve activation. By contrast, these effects failed to be observed in long-term caffeine intake. Importantly, long-term administration of caffeine lowered blood pressure, which was not associated with sympathetic nerve activation and cardiovascular changes in Dahl-S rats. It suggested that chronic hypotensive effects of caffeine could be caused by its natriuretic effects in Dahl-S rats. Some studies have reported that systolic blood pressure, rather than diastolic blood pressure, are affected by urinary sodium excretion^{40,41}. This may partially explain why caffeine failed to prevent high salt induced increase in diastolic blood pressure in our study. In addition, a recent study also showed that ambulatory systolic blood pressure was inversely correlated with urinary caffeine and its metabolites in adults from a general population, which indicated a potential protective effect of caffeine on blood pressure⁴². Thus, chronic caffeine intake might be an effective lifestyle intervention to promote salt excretion in people who normally consume a high salt diet. However, its application in human still warrants further determination in future.

In conclusion, we have demonstrated that chronic caffeine intake prevents salt-sensitive hypertension in Dahl-S rats. The beneficial effect of caffeine is associated with activation of renal AMPK that inhibits ENaC activity, which subsequently increases urinary sodium excretion and maintains blood pressure during high salt

Figure 4. Chronic caffeine intake decreases the expression and function of α ENaC in Dahl's rats.

(a) Western blot analysis of cortical collecting duct lysates. Chronic caffeine intake decreased α ENaC expression without significant influence on β ENaC, γ ENaC and sodium chloride cotransporter (NCC) expression ($n = 6$). (b) Representative curves (left panel) show the individual 24-hour UNaV of rats in control group and caffeine group before and after amiloride injection (3 mg/kg, intraperitoneal). The columns (right panel) show the changes in 24-hour UNaV after amiloride injection ($n = 8$). (c) Representative curves (left panel) show the individual 24-hour UNaV of rats in control group and caffeine group before and after hydrochlorothiazide (HCTZ) injection (3 mg/kg, intraperitoneal). The columns (right panel) show the changes in 24-hour UNaV after HCTZ injection ($n = 8$). All data are presented as means $\pm$ SEM. * $P < 0.05$ compared with control.

diet. However, chronic effect of caffeine on animal models needs to be further validated in human. These findings provide insight into the physiological role of caffeine in a long-term regulation of blood pressure through affecting renal sodium handling.

Figure 5. Caffeine decreases the expression and activity of αENaC in M1-CCD cells. (a) Western blot analysis showed that incubation with caffeine (10 mM) for 24 hour significantly decreased αENaC expression and increased αAMPK expression without significant impact on SGK1, ERK1/2 and PKCα expression (n = 6). (b) Incubation with caffeine (Caf, 1 mM to 10 mM) dose-dependently decreased ENaC expression in M1-CCD cells, but increased AMPK and phospho-AMPK expression in M1-CCD cells. Compound C (C, 1 μM) abolished the effect of caffeine on ENaC, AMPK and phospho-AMPK expression. (n = 5). (c) Representative single-channel ENaC traces recorded from two groups of M1-CCD cells by using saline or caffeine to the basolateral bath; downward events represent channel openings; the currents were monitored for at least 30 min. (n = 8). NPo, the product of the number of channels and the open probability was used to measure the channel activity within a patch. All data are presented as means ± SEM. *P < 0.05 compared with control, **P < 0.01 compared with control.

Materials and Methods

Animal Treatment. Six-week-old male Dahl salt-sensitive rats (Dahl-S) were obtained from Vital River Company, Beijing, China and housed under controlled temperature (21–23 °C) with a 12/12 hr light-dark cycle with free access to food and water. Animals were anesthetized by inhaling of 2% isoflurane (v/v), and surgically implanted with BP telemetric transmitters (TA11PA-C40, Data Sciences International, Minnesota, USA). After recovering from the surgery for 10 days, animals were randomly assigned to two groups: The control group was given a high salt chow containing 8% (w/w) NaCl and normal drinking water. The caffeine group was fed the 8% NaCl chow and 0.1% caffeine in their drinking water. The dietary intervention lasted 15 days. All of the experimental procedures were performed in accordance with protocols approved by Institutional Animal Care and Use Committee of the Institute of Third Military Medical University, and all experiments were performed in accordance with the National Institutes of Health guidelines for the use of experimental animals.

Blood pressure and locomotor activity measurement. 24-hour ambulatory blood pressures and locomotor activity were measured by radiotelemetry in conscious, unrestrained rats as previously described⁴³. We collected data for 10 seconds every 30 minutes and used the mean values of 24 hours for the analysis.

Urinary Samples Analysis. On the 16th day, rats were transferred to individual metabolic cages (Tecniplast, Italy). Both groups maintained the same dietary intervention as mentioned before and had free access to food and water. The 24-hr water consumption and urinary excretion of water and sodium were measured. Urinary sodium concentrations were measured using a flame photometer (Spectrum, Shanghai China). Urinary sodium excretion (UNaV) was calculated by this formula: UNaV = [urine sodium concentration] × [24-hour urine volume].

Vascular Reactivity and Electrical Field Stimulation. Vascular reactivity and electrical field stimulation were performed as previously described⁴⁴. After rats were anesthetized with pentobarbital sodium (100 mg/kg body weight ip), the mesenteric vascular bed was removed and placed in a cold (4 °C) Krebs solution containing (mM): 118 NaCl, 25 NaHCO₃, 11 D-glucose, 4.7 KCl, 1.2 KH₂PO₄, 1.17 MgSO₄, and 2.5 CaCl₂. The second branches of mesenteric arteries were dissected out and the connective tissue was removed. The arterial segments (2–2.5 mm in length) were mounted in a myograph. Vascular rings were bathed in Krebs solution aerated with 95% O₂ and 5% CO₂ at 37 °C (pH 7.4) and were stretched to the optimum baseline tension (2.5 mN). The rings were equilibrated for 60 min before the start of an experiment. High K⁺ (60 mM)-containing Krebs solution was added to test contractility. Isometric contractions were recorded using a computerized data acquisition system (PowerLab/8SP; AD Instruments Pty Ltd., Castle Hill, Australia).

Electrical Field Stimulation (EFS) was achieved using a stimulator (Grass SD9) connected to two platinum electrodes placed on each side of the ring parallel to its longitudinal axis. The frequency–response curves (2–32 Hz, 30 V, 30 s trains and 1 ms duration) were obtained. There was an interval of 1 min between each stimulus to allow for recovery of basal tone. To evaluate the neural origin of the EFS-induced contractile response, the nerve impulse propagation blocker, tetrodotoxin (TTX, 0.1 mM), was added to the bath 30 min before the second frequency-response curve was determined.

Preparation of renal cortical collecting duct. Rats were anesthetized with sodium pentobarbital (100 mg/kg body weight ip), the circulatory system was perfused via the left ventricle with Eagle's minimal essential medium (MEM) containing collagenase (1 mg/ml), soybean trypsin inhibitor (2 µg/ml), aprotinin (2 µg/ml). After perfusion, kidneys were removed, cut into coronal slices, and incubated for 10–15 min at 37 °C in the same solution used for the perfusion. After collagenase washout, slices were kept in ice-cold MEM containing soybean trypsin inhibitor (2 µg/ml) throughout the microdissection procedure. The renal cortical collecting duct (CCD) segments were separated manually using fine forceps and identified with characteristic branching indicative of CCDs. The pools of CCDs containing 10–20 microdissected tubules with the total tubular length of ~10 mm/pool were transferred in 5 µl of Dulbecco's modified Eagle's medium (DMEM)/ Ham's F-12 (1:1) medium into 1.5 ml of Eppendorf tubes and refrigerated in –70 °C for protein extraction⁴⁵.

The amiloride and hydrochlorothiazide test. Another group of rats were used to evaluate the effect of caffeine on ENaC and NCC function at distal nephron. The procedure of fifteen-day's dietary intervention was the same as mentioned at Animal Treatment section. After that rats were transferred to metabolic cages. A 24-hr urine samples were collected in metabolic cages. Then the rats were administrated of amiloride (3 mg/kg, ip), an ENaC antagonist, or hydrochlorothiazide (12.5 mg/kg, ip), a NCC antagonist. After the amiloride or hydrochlorothiazide administration, another 24-hr urine samples were collected. Urinary sodium concentrations were measured using a flame photometer (Spectrum, Shanghai China).

M1-CCD Cells Culture. The renal cortical collecting duct M1-CCD cell line was purchased from American Type Culture Collection (CRL-2038; American Type Culture Collection, Manassas, VA). M1-CCD cells were cultured in DMEM/F-12 (1:1) medium with FBS (5%) supplemented with L-glutamine (2 mM), penicillin (100 mg/ml), streptomycin (100 U/ml), and dexamethasone (5 mM) and grown at 37 °C in a 5% CO₂ humidified incubator. Quiescent cells were obtained by serum free medium incubation for 12 hr before treatment of caffeine (Sigma, series number: 93784) and the AMPK inhibitor Compound C (Calbiochem, series number: 171260).

Western Blotting analysis. Western blotting analysis was performed using standard procedures as previously described⁴⁶. The antibodies against αENaC (sc-21012), βENaC (sc-21013), γENaC (sc-21014), SGK1 (sc-28338), ERK1/2 (sc-135960), PKCα (sc-8393), AMPKα (sc-25792) and phosphor-AMPKα (sc-33524) were purchased from Santa Cruz Biotechnology (Santa Cruz, CA, USA). The NCC antibody (AB3553) was a product of Millipore (Merck Millipore Corporation, Darmstadt, Germany) and the internal control GAPDH antibody

(KC-5G5) was purchased from Kang Chen Bio-tech Incorporation, China. Transferred PVDF membranes were incubated with primary antibodies at 4 °C for 12 hr. After incubation with secondary antibodies (ZSGB-BIO, China) at room temperature for 2 hr, the proteins were detected with enhanced chemiluminescence and quantified using a Gel Doc 2000 Imager (Bio-Rad, USA). The protein levels were normalized to the internal control GAPDH.

Electrophysiology. For single channel recordings of ENaC, M1-CCD cells were studied under voltage-clamp conditions using standard methods as previously described. A patch pipette with the resistance of 6–8 MΩ was fabricated from a borosilicate glass capillary (1.5 mm od, 0.86 mm id, Sutter Instrument, Germany) on a Sutter Puller (P97, Sutter Instrument, Germany). The bath solution was (in mM): 110 NaCl, 4.5 KCl, 1 MgCl₂, 1 CaCl₂, 5 Hepes, 5 Na-Hepes (pH 7.2) with a pipette solution of: 110 NaCl, 4.5 KCl, 0.1 EGTA, 5 Hepes, 5 Na-Hepes (pH 7.2). Single-channel currents were recorded using an EPC-10 patch-clamp amplifier (HEKA Instrument, Germany) and PATCHMASTER 8.0 software (HEKA Instruments, Germany). The data were acquired by application of 0 mV pipette potential and were sampled at 5 KHz and low-pass filtered at 1 KHz. During *post hoc* analysis, data were further filtered at 50 Hz and single-channel events were listed and analyzed by clamp fit 10.2 software (Molecular Devices, Sunnyvale, CA, USA). The total number of functional channels in a patch was determined by observing the number of peaks detected on the current amplitude histograms during at least 10-min recording period. NPo, the product of the number of channels and the open probability, or the open probability (Po) of ENaC before and after application of test agents was calculated using Clampfit 10.2 (Molecular Devices, Sunnyvale, CA, USA). In single-channel records, the control ENaC activity was recorded for 3–4 min after forming the cell-attached mode and ENaC activity had stabilized. We usually recorded at least 30 min of any experimental manipulation.

Statistical Analysis. All data are expressed as mean ± SEM. Statistical significant differences between two groups were evaluated by means of Mann-Whitney U tests. P values < 0.05 were considered to be statistically significant.

Acknowledgements

This study was funded by the National Natural Science Foundation of China (31430042) and the National Basic Research Program of China (2013CB531205 and 2012CB517805), National Natural Science Foundation of China (91339112 and 91439000), the Program for Changjiang Scholars and Innovative Research Team in University (IRT1216) and NIH grant number (HL-02334). We thank Lijuan Wang (Chongqing Institute of Hypertension, China) for technical assistance.

Author Contributions

H.Y. and T.Y. performed the experiments, analyzed the data and wrote the manuscript. P.G. performed the experiments, analyzed the data and revised the manuscript. X.W., H.Z., S.X., Z.L., L.L., X.W., J.C. and Y.Z. helped with performing some experiments. W.J.A. and Q.S. gave suggestions on the discussion section. Q.S., D.L. and Z.Z. were responsible for the study design and reviewed the manuscript. All authors have read and approved the final version of the manuscript.
