The electronic structure and optical absorption spectrum of organometal halide perovskite compound $\text{CH}_3\text{NH}_3\text{BiI}_3$ as a substituting candidate of well-concerned $\text{CH}_3\text{NH}_3\text{PbI}_3$ not only for environmental friendly consideration are studied using the first principles calculations. It is revealed that a Bi replacement of Pb in $\text{CH}_3\text{NH}_3\text{PbI}_3$ does not change seriously the band edge structure but the bandgap becomes narrow. Consequently, $\text{CH}_3\text{NH}_3\text{BiI}_3$ exhibits not only stronger visible light absorption than $\text{CH}_3\text{NH}_3\text{PbI}_3$ does but more strong absorption in the infrared region, which is however absent in $\text{CH}_3\text{NH}_3\text{PbI}_3$. It is suggested that $\text{CH}_3\text{NH}_3\text{BiI}_3$ may be one of even more promising alternatives to $\text{CH}_3\text{NH}_3\text{PbI}_3$ for spectrum-broad and highly-efficient solar cells.

Photovoltaic (PV) effect is an ideal photoelectric energy conversion process^{1,2} and has been one of the major mechanisms for green energy utilization in past decades, benefiting to human life substantially. The photoelectric conversion efficiency and cost-competitive manufacturing represent two major issues for PV researches and industry. At present, the photoelectric conversion efficiency of solar cells based on semiconducting materials such as Si and GaAs *et al* is between 12~25%³, driving sustained search for additional PV materials which are more cost-competitive and more easily processed without much damage to environment. The emergency of organometal halide perovskite compound $\text{CH}_3\text{NH}_3\text{PbI}_3$ as the absorbing layer in recent years seems to be a milestone-like breakthrough for solar cell materials researches⁴⁻⁶. Successively broken records in the photoelectric conversion efficiency as reported on $\text{CH}_3\text{NH}_3\text{PbI}_3$ have been made. So far recorded efficiency has reached up to 20.2% from the original 3.8%. Moreover, the production cost of such perovskite-type compounds for solar cells is low, also stimulating development of a series of other organometal halide perovskites derivatives of $\text{CH}_3\text{NH}_3\text{PbI}_3$ ⁷⁻⁹. These events quickly have driven vigorous researches over the world.

Great amount of research in the past few years has comprehended several major issues. First, it is known that the diffusion lengths of electrons and holes in $\text{CH}_3\text{NH}_3\text{PbI}_3$ and its derivatives are quite big¹⁰, thus establishing these compounds as high efficiency solar cell materials. For examples, Stranks *et al.*¹¹ measured the electron and hole diffusion lengths using the photoluminescence quenching method, and found that the photon-generated carriers in $\text{CH}_3\text{NH}_3\text{PbI}_3$ has ~100 nm in diffusion length. This length can be further enhanced for photon-generated carriers in $\text{CH}_3\text{NH}_3\text{PbI}_{3-x}\text{Cl}_x$, which is more than 1.0 μm , suggesting that the halogen family substitution or doping represents an effective and common strategy to improve the photoelectric performances. Second, the electronic structure of this compound family has been investigated. By using the light absorption test method, Grätzel *et al.* determined the binding energy to be ~30 meV for photon-generated carriers in $\text{CH}_3\text{NH}_3\text{PbI}_3$ ¹², while the value determined by Sun *et al.* is ~19 meV¹³. Such a small binding energy allows the spontaneous separation of the carriers into free electrons and holes at room temperature. Third, the electrical transport behaviors of $\text{CH}_3\text{NH}_3\text{PbI}_3$ were found to be sensitive to processing conditions, and the carriers can be dominated by electrons or holes, as predicted by the first principles calculations. Fourth, the defect states in $\text{CH}_3\text{NH}_3\text{PbI}_3$ were identified to impose substantial influence on the materials performances. It was reported that the defect formation energy for shallow defect states can be relatively small, while those deep defect states can have very large defect formation

energy. This big difference explains why $\text{CH}_3\text{NH}_3\text{PbI}_3$ has a big electron-hole scattering length and high open circuit voltage¹⁴.

Here, element substitution of $\text{CH}_3\text{NH}_3\text{PbI}_3$ has been highly concerned since this strategy allows additional opportunities via electronic structure modulation and carrier density control to improve practical performances of these compounds for solar cell applications. Along this line, halogen element replacement and partial substitution in $\text{CH}_3\text{NH}_3\text{PbI}_3$, as described above, have been repeatedly tried. In fact, it was reported that a Cl substitution of I in $\text{CH}_3\text{NH}_3\text{PbI}_3$ allows the formation of $\text{CH}_3\text{NH}_3\text{PbI}_{3-x}\text{Cl}_x$ ^{7,15}, whose bandgap remains similar to that of $\text{CH}_3\text{NH}_3\text{PbI}_3$ but the positions of conduction band and valence band are modulated, leading to great promotion of diffusion and transport of carriers and thus benefiting to conversion efficiency enhancement. By using light luminescence quenching experiment, Stranks *et al.* reported a diffusion length more than 1.0 μm for photon-generated carriers in $\text{CH}_3\text{NH}_3\text{PbI}_{3-x}\text{Cl}_x$ ¹⁰. In parallel to that, Xiao *et al.* replaced a replacement of I by Br to synthesize the $\text{CH}_3\text{NH}_3\text{PbBr}_3$ ⁸. It was found that the high conduction band energy level of $\text{CH}_3\text{NH}_3\text{PbBr}_3$ can effectively enhance the open circuit voltage (V_{oc}) of solar cells¹⁶, but the big bandgap of $\text{CH}_3\text{NH}_3\text{PbBr}_3$ makes visible light absorption window narrow. At the same time, the large binding energy of photon-generated carriers of $\text{CH}_3\text{NH}_3\text{PbBr}_3$ makes it difficult to spontaneously separate the carriers into free electrons and holes¹⁵.

In addition to the halogen substitution strategy, lattice reconstruction was believed to be effective too in improving the optical absorption properties of $\text{CH}_3\text{NH}_3\text{PbI}_3$. Feng *et al.* successfully constructed the orthorhombic and tetragonal phases of $\text{CH}_3\text{NH}_3\text{PbI}_3$, and calculated the optical absorptions of the two phases using the Heyd-Scuseria-Ernzerhof (HSE) screened hybrid functional (HSE06)⁸. Subsequently, the optical absorption spectra of the two phases were calculated using the quasi-particle GW correction method and multi-body interaction method¹⁷. Experimentally, substantial efforts have been made to probe the electronic structures and optical properties of $\text{CH}_3\text{NH}_3\text{PbX}_3$ ($\text{X} = \text{I}, \text{Br}, \text{Cl}$)^{8,10}.

Different from the above two approaches, the cationic Pb occupation in $\text{CH}_3\text{NH}_3\text{PbX}_3$ ($\text{X} = \text{I}, \text{Cl}, \text{Br}$) has been thought to be irreplaceable, while the underlying reasons for this irreproducibility seems entangled to us. Either theoretical or experimental trial on replacement of Pb is still lacking. It is suggested that the upper valence band

dispersion of CH₃NH₃PbI₃ consists mainly of strong anti-bonding coupling of Pb-*s* and I-*p* orbitals. The strong *s-p* anti-bonding coupling makes the effective mass of holes close to that of electrons, enabling the quite big diffusion length for electron-hole pairs¹², which is definitely unusual for solar cell applications. Nevertheless, Pb atom is a heavy metal which pollutes the environment and utilization of Pb is being strictly regulated world widely. It is immediately noted that the Bi-*s* orbital shows quite similar feature as that of the Pb-*s* orbital, making a replacement of Pb by Bi attractive for exploration. In such sense, CH₃NH₃BiI₃ is likely to be a good candidate for solar cell devices, noting that Bi is non-toxic, abundant in earth, and has similar atomic properties as Pb.

In this work, our main motivation is to investigate the electronic structure and optical absorption of CH₃NH₃BiI₃ as a generic substitute of CH₃NH₃PbI₃ in terms of solar cell absorption properties. This motivation stems from two aspects. One is that CH₃NH₃BiI₃ may exhibit broad optical absorption spectrum extending to infrared region. The other is that it is environment-friendly and cost-competitive. We employ the first-principles calculation based on the density functional theory (DFT) to study the band structure and optical absorption spectrum. The details for first-principles calculations are described in Sec. II, and the calculated results are presented and discussed in Sec. III. A brief conclusion is given in Sec. IV.

Models and Computation Details

All calculations are performed using the Vienna *ab initio* simulation package (VASP5.2) code based on the density functional theory (DFT)^{18,19}. The exchange and correlation potential are modeled using the generalized gradient approximation (GGA) Perdew-Becke-Erzenhof (PBE) function²⁰. In standard procedure, the interaction of valence electrons with ionic core is described using the projector augmented wave (PAW) method²¹, and the wave function of the valence electron is unfolded by plane wave basis using a cutoff energy of 400 eV¹⁴.

Figure 3. The calculated band structures of O-CH₃NH₃PbI₃ (a), O-CH₃NH₃BiI₃ (b), T-CH₃NH₃PbI₃ (c), and T-CH₃NH₃BiI₃ (d). The red dashed lines represent the Fermi level.

It is noted that CH₃NH₃BiI₃ is yet a proposed compound and so far no data on its synthesis and lattice structure are available. It is noted that for a stable perovskite ABX₃, the ion radius ratio $((r_A + r_X)/\sqrt{2}(r_B + r_X))$ is required to be close to 1 and thus the size of A atom is much larger than that of atom B. The large-size organic ion CH₃NH₃⁺ can effectively stabilize this perovskite structure but does not make considerable contribution to the electronic structure of CH₃NH₃PbI₃ around the band edge. For CH₃NH₃BiI₃, the large-size organic ion CH₃NH₃⁺ which can effectively stabilize this perovskite structures does not change. In this sense, CH₃NH₃BiI₃ is the same as CH₃NH₃PbI₃ and should have very stable crystal structure in ambient device processing conditions. So, our calculation then starts from the structural data on reference compound CH₃NH₃PbI₃. CH₃NH₃PbI₃ has the orthorhombic phase and tetragonal phase, while the structure data package was successfully constructed by Feng *et al.*⁸. The structures of the two phases are shown in Fig. 1 (for simplicity, herein we denote the orthorhombic and tetragonal CH₃NH₃XI₃ as O-CH₃NH₃XI₃ and T-CH₃NH₃XI₃ respectively). Along this line, we start from experimentally given data on CH₃NH₃PbI₃ and then Bi substitution of Pb is performed, followed by sufficient structural relaxation and optimization.

The two configurations of crystal cell both contain 48 atoms. For orthorhombic and tetragonal structures, the *k*-point grids are set to 5 × 5 × 5 and 7 × 7 × 5 for the Brillouin zones respectively using the Monkhorst-Pack scheme²². For the optimization, the structures are fully relaxed until the Hellmann-Feynman force acting on each atom is reduced down to 10 meV/Å, and the energy convergence threshold is set as 1.0 × 10⁻⁶ eV/atom. The normal generalized gradient approximation (GGA) is employed although CH₃NH₃PbI₃ was reported to have the spin-orbital coupling (SOC) effect because of the strong relativistic effect of Pb²³. However, it is known that the GGA method usually underestimates the band gap, which can offset exactly the ignored SOC effect with each other in occurrence²⁴. This implies that the GGA method can give accurate bandgap of CH₃NH₃XI₃, and thus the SOC will not be considered in our calculations.

Results

Structure optimization. In our calculations, we always take CH₃NH₃PbI₃ as the reference for CH₃NH₃BiI₃. The optimized structures of O-CH₃NH₃PbI₃ and T-CH₃NH₃PbI₃ respectively are obtained and the lattice constants are listed in Table 1, where measured and earlier predicted values on CH₃NH₃PbI₃ are inserted too for comparison. It is seen that our calculated data are roughly consistent with those measured and earlier predicted values, indicating the reliability of the present computational scheme^{25,26}. To the conventional stage, such differences are reasonably acceptable due to the relatively loose organic-inorganic hybrid structure. One sees that the Bi

Figure 4. Calculated density of states of $\text{O-CH}_3\text{NH}_3\text{PbI}_3$ and $\text{O-CH}_3\text{NH}_3\text{BiI}_3$, (a) TDOS, (b) PDOS. The red dashed lines represent the Fermi level.

replacement of Pb does not induce remarkable variation of the lattice constants. The $\text{O-CH}_3\text{NH}_3\text{BiI}_3$ has slightly tensioned a -axis and compressed b -axis with respect to the $\text{O-CH}_3\text{NH}_3\text{PbI}_3$. For the $\text{t-CH}_3\text{NH}_3\text{BiI}_3$, the a -axis is slightly tensioned but the c -axis is a little compressed. Considering the different definitions of lattice major axes for the two phases, the consequence of Bi replacement of Pb induces negligible variations of the lattice constants.

Nevertheless, no deterministic dependence of the three lattice constants on cation species at X site (Pb or Bi) can be evaluated from the data in Table 1. Alternatively, we consult to the six X-I bond lengths of the XI_6 octahedra in order to see the differences between the two compounds and bond lengths of the XI_6 octahedra are listed in Table 2. It is interested to notice that for $\text{O-CH}_3\text{NH}_3\text{BiI}_3$ and $\text{T-CH}_3\text{NH}_3\text{BiI}_3$, all the six Bi-I bonds are shorter than the corresponding Pb-I bonds of $\text{O-CH}_3\text{NH}_3\text{PbI}_3$ and $\text{T-CH}_3\text{NH}_3\text{PbI}_3$. In addition, the differences in XI_6 octahedron distortion between the two compounds are distinct either. In order to see more clearly, we project the planar projections of the optimized structures (phases) and the results are presented in Fig. 2. First, the (010) plane projections of $\text{O-CH}_3\text{NH}_3\text{PbI}_3$ and $\text{O-CH}_3\text{NH}_3\text{BiI}_3$, presented in Fig. 2(a) and (b), respectively, show that the PbI_6 octahedra rotate along the b -axis with serious distortion. The four octahedron centers within the projection plane constitute a diamond configuration. Very differently, $\text{O-CH}_3\text{NH}_3\text{BiI}_3$ structure exhibits nearly no BiI_6 octahedron distortion, and the four octahedron centers within the projection plane forms a square shape. The orientations of organic ion groups CH_3NH_3^+ in the two compounds are different either.

The (001) plane projected configurations of $\text{T-CH}_3\text{NH}_3\text{PbI}_3$ and $\text{T-CH}_3\text{NH}_3\text{BiI}_3$ are plotted in Fig. 2(c) and (d) respectively. Again, the XI_6 octahedra for both compounds have remarkable distortion which is more serious for $\text{T-CH}_3\text{NH}_3\text{PbI}_3$. The significant difference is that the twists of the upper and lower PbI_6 octahedra are not synchronous, but the BiI_6 octahedra exhibit the synchronous twisting which leads to the coincidence of the upper and lower octahedron. At the same time, these octahedron distortion results in very different configurations of CH_3NH_3^+ groups in the two structures, which certainly make the electronic structure quite different, to be shown below. Here, what should be mentioned here is that a more seriously distorted lattice usually favors stronger carrier localization and thus bigger bandgap. The charge transport in $\text{CH}_3\text{NH}_3\text{BiI}_3$ is much easier due to the much weaker localization for charges in $\text{CH}_3\text{NH}_3\text{BiI}_3$ than in $\text{CH}_3\text{NH}_3\text{PbI}_3$. $\text{CH}_3\text{NH}_3\text{BiI}_3$ would have better photoelectric properties than $\text{CH}_3\text{NH}_3\text{PbI}_3$, which fits to our motivation on investigating $\text{CH}_3\text{NH}_3\text{BiI}_3$ as a promising candidate for solar cell applications.

Electronic structure. Given the optimized lattice structure for $\text{CH}_3\text{NH}_3\text{BiI}_3$, one is allowed to evaluate the band structure. First, the calculated band structures for the O-phase and T-phase are plotted in Fig. 3, where the red dashed lines represent the Fermi levels in each case. The presented results can be discussed from several aspects.

First, both compounds in the o-phase are direct band gap semiconductors as seen at the G points of the Brillouin zone. The bandgap of $\text{O-CH}_3\text{NH}_3\text{PbI}_3$ is ~ 1.68 eV, similar to results obtained by previous theoretical predictions⁸, while measured gap values are smaller due to the inevitable defect states. The Fermi level locates at

Figure 5. Calculated density of states of T-CH₃NH₃PbI₃ and T-CH₃NH₃BiI₃, (a) TDOS, (b) PDOS. The red dashed lines represent the Fermi level.

the valence band maximum (VBM), indicating the nature of *p*-type semiconductor, while experimental measurements often reported the *n*-type semiconducting behaviors, most likely due to the defect states in samples¹⁴. So, lead halide perovskite CH₃NH₃PbI₃ can be tuned from good *p*-type to good *n*-type by controlling the growth conditions. The bandgap of O-CH₃NH₃BiI₃ is ~1.05 eV. Since Bi atom has one more electron outermost than Pb atom, the Fermi level shifts into the conduction band minimum (CBM), which makes CH₃NH₃BiI₃ metallized. It is noted that such a crossing of the Fermi level with the CBM does not imply real metallization, due to the fact that there still have the energy excitation greater than the band gap energy^{27–29}. Therefore, O-CH₃NH₃BiI₃ remains to be an *n*-type degenerate semiconductor. Same to CH₃NH₃PbI₃, CH₃NH₃BiI₃ might be tuned from *n*-type to *p*-type by controlling the growth conditions because the thermodynamic stable range for equilibrium growth of the material cover a long shape of chemical potential region¹⁴. Second, as shown in Fig. 3(c) and (d) respectively, the T-CH₃NH₃PbI₃ is also a *p*-type direct bandgap semiconductor with gap of ~1.58 eV, similar to earlier predictions⁸. The band structure details are similar to those of the o-phase. For T-CH₃NH₃BiI₃, a direct band gap of ~1.14 eV is identified, which is 0.09 eV smaller than that of the o-phase. The Fermi level is again above the CBM, exhibiting the *n*-type degenerate semiconducting behavior.

In the overall sense, both O-CH₃NH₃BiI₃ and T-CH₃NH₃BiI₃ have much less lattice distortion and smaller bandgap than O-CH₃NH₃PbI₃ and T-CH₃NH₃PbI₃ respectively. When the band gap becomes smaller, the charge recombination chances also increases. However, a smaller band gap either allows enhanced optical excitation. In the overall sense, the number of photo-generated electron-hole pairs still increase, benefiting to the photo-voltaic performance. A preliminary prediction, consistent with the analysis on lattice structure, is that CH₃NH₃BiI₃ should have better optical absorption performance than CH₃NH₃PbI₃. The *n*-type carriers in CH₃NH₃BiI₃ also provide alternative choice for practical applications.

To further look into the details of electronic structure, we calculate the total density of states (TDOS) and projected density of states (PDOS) of CH₃NH₃PbI₃ and CH₃NH₃BiI₃ in the two phases respectively and the results are plotted in Fig. 4. The red vertical dashed line marks the Fermi level. For the o-phase, the two compounds exhibit similar TDOS profiles, as shown in Fig. 4(a). The main difference appears in the deep valence band ranging from -5.0 eV ~ -9.0 eV. It is generic to expect the similar photoelectric properties between the two compounds since electronic structure features around the conduction and valence bands are roughly the same. Figure 4(b) plots the PDOS profiles of the two compounds in the o-phase. Because the most important role of the big-size organic ion group CH₃NH₃⁺ is to stabilize the organic metal structure and denote an electron, one is allowed to argue nearly no contribution from the CH₃NH₃⁺ to the valence and conduction bands.

We first discuss the data on O-CH₃NH₃PbI₃, as shown in Fig. 4(a), as a reference for subsequent discussion on O-CH₃NH₃PbI₃. The O-CH₃NH₃PbI₃ has a ~1.68 eV bandgap between empty Pb-*p* orbital and fully-occupied I-*p* orbital. The CBM mainly consists of Pb-*p* orbital which has nearly no coupling with I orbital, indicating the Pb-I ionic bond nature. The upper valence band mainly consists of fully-occupied Pb-*s* orbital with strong antibonding coupling with I-*p* orbital. Such band edge features were reported earlier^{14,30,31}. The strong *s*-*p* antibonding

Figure 6. Calculated electron density O-CH₃NH₃PbI₃ (a), O-CH₃NH₃BiI₃ (b); the electron density difference for O-CH₃NH₃PbI₃ (c), O-CH₃NH₃BiI₃ (d). Contours show the values in a slice of the (010) plane. The units are electrons Å⁻³. In panels (a,b), Color from blue to red represent electron density changes from low to high. In panels (c,d), Color red (blue) represent the electron density increased (decreased).

coupling leads to very small effective mass of holes, comparable with electron effective mass. This is the reason why CH₃NH₃PbI₃ is an ideal candidate for *p-i-n* configuration thin-film solar cells¹⁴.

For O-CH₃NH₃BiI₃, the bandgap physics shows some similarities and differences. First, the gap appears between partially-occupied Bi-*p* orbital and fully-occupied I-*p* orbital, while the CBM mainly consists of Bi-*p* orbital. The Bi-*p* orbital has either nearly no coupling with I orbital, indicating the nature of Bi-I ionic bonding. The fully-occupied Bi-*s* orbital is coupled with the I-*p* orbital in strong-antibonding form, allowing small effective mass of holes which is comparable with that of electrons in O-CH₃NH₃PbI₃. In this sense, O-CH₃NH₃BiI₃ can be an ideal absorbing layer for thin-film solar cells alternative to O-CH₃NH₃PbI₃. Furthermore, O-CH₃NH₃BiI₃ has smaller bandgap and thus enables better optical absorption performance than O-CH₃NH₃PbI₃. Finally, one comes to the TDOS and PDOS of T-CH₃NH₃BiI₃ while those of T-CH₃NH₃PbI₃ are inserted for comparison too, as shown in Fig. 5. While delicate difference in details of the TDOS and PDOS with the results of o-phases, highly similarity of major features between two T-phases is seen immediately.

We further consult to the calculated charge density and charge density difference for the two compounds, and the results for the O-phases are plotted in Fig. 6 illustrating the charge density on the equatorial plane of XI₆ octahedron. First, clear octahedral distortion in O-CH₃NH₃PbI₃ can be identified, consistent with earlier prediction²⁵. The Pb-I ionic bonding feature is also significant. The octahedral distortion and ionic bonding in O-CH₃NH₃BiI₃ are however relatively weaker. Second, the charge density in the region between Pb core and I core is less than that between Bi core and I core, and the reason is also obvious since Bi atom has one more outermost valence electron than Pb atom and the excess electron will mainly distribute on the I-*p* and Bi-*p* orbitals along the Bi-I direction. This feature enables the stronger covalent bonding character between Bi-I pair than that between Pb-I pair. Nevertheless, it should be mentioned that the Bi-I and Pb-I pair in these two materials are ionic bond dominant. A stronger covalent character between Bi-I pair only show more extensive charge spatial distribution rather than more electronic shackles. In this sense, the charges in CH₃NH₃BiI₃ would show better transport performance. Third, a look at the charge density difference shown in Fig. 6(c) and (d) allows several more features. One sees that Pb loses electrons less along the Pb-I direction while the areas that Pb loses electrons most mainly appear in the four I-Pb-I sector regions divided by two neighboring I atoms and central Pb atom. I ion gets electrons most along the I-Pb direction. One also sees three strong gaining electronic regions around I ion on equatorial plane

Figure 7. Calculated optical absorption spectrum of O-CH₃NH₃XI₃ (Pb, Bi), (a), and T-CH₃NH₃XI₃ (Pb, Bi) (b).

due to the torsion of PbI₆ octahedron. Similarly, Bi loses electrons less along the Bi-I direction, and the areas that Bi loses electrons most mainly locate in the four I-Bi-I sector regions divided by two neighboring I atoms and central Bi atom. Although I atom gets electrons most along the I-Bi direction, here one sees four strong gaining electronic regions around I atom on equatorial plane, due to the fact that BiI₆ octahedron has much less torsion.

Optical properties. The major consequence to be expected from the above presented results is the much better optical absorption performance of CH₃NH₃BiI₃ than CH₃NH₃PbI₃. We use the linear response method to calculate the macroscopic optical response function described by complex dielectric function. The complex dielectric function $\epsilon(\omega) = \epsilon_1(\omega) + i\epsilon_2(\omega)$ contains real part $\epsilon_1(\omega)$ and imaginary part $\epsilon_2(\omega)$, where $\epsilon_2(\omega)$ can be obtained by calculating the momentum matrix elements between the occupied and unoccupied wave functions. Consequently, $\epsilon_1(\omega)$ is calculated from $\epsilon_2(\omega)$ using the Kramer–Kronig relationship³². It is noted that the optical absorption spectrum is characterized by the optical constant which is related with the dielectric function $\alpha(\omega) = \frac{\omega}{C} [2[\sqrt{\epsilon_1^2(\omega) + \epsilon_2^2(\omega)} - \epsilon_1(\omega)]]^{\frac{1}{2}}$, where α is the absorption coefficient, C the speed of light, ω the circular frequency.

The calculated optical absorption spectrum for the O-phase and T-phase of CH₃NH₃PbI₃ and CH₃NH₃BiI₃ are plotted in Fig. 7(a) and (b), noting that visible light energy appears in 1.64 eV~3.19 eV, as marked out in the inset using green oblique lines. No matter what phase it is, one sees two major consequences. First, for CH₃NH₃BiI₃, the long-wavelength boundary is substantially extended toward the infrared region, in which the optical absorption is significant as seen more clearly in the two insets. Second, CH₃NH₃BiI₃ has even better absorption performance in the visible region than CH₃NH₃PbI₃. The two characters of CH₃NH₃BiI₃ suggest that using Bi to replace Pb in CH₃NH₃PbI₃ would be a highly favored strategy, while CH₃NH₃BiI₃ is expected to be a promising candidate for highly efficient absorption media for solar cell devices.

Discussions

In this paper, we have carefully calculated the electronic structures and optical properties of organometal halide perovskites materials CH₃NH₃XI₃ (X = Pb, Bi) using the first principle calculation. Our results indicate that CH₃NH₃PbI₃ is a direct band gap semiconductor. The strong antibonding coupling state of Pb-s orbital and I-p orbital compose of the top of the valence band distribution. For CH₃NH₃BiI₃, the band gap is narrow with respect to CH₃NH₃PbI₃. The strong antibonding coupling states of Bi-s orbital and I-p orbital compose of the top of the valence band distribution of CH₃NH₃BiI₃, and the band edge structure is similar to that of CH₃NH₃PbI₃. The optical data show that CH₃NH₃BiI₃ has stronger visible light absorption than CH₃NH₃PbI₃ and infrared absorption is predicted. These similar electronic structures and better spectral absorption indicate that CH₃NH₃BiI₃ system is likely to be a good candidate for solar battery.
