Direct observations using scanning transmission electron microscopy unveil an intriguing interfacial bi-layer that enables epitaxial growth of a strain-free, monoclinic, bronze-phase VO₂(B) thin film on a perovskite SrTiO₃ (STO) substrate. We observe an ultrathin (2–3 unit cells) interlayer best described as highly strained VO₂(B) nanodomains combined with an extra (Ti,V)VO₂ layer on the TiO₂ terminated STO (001) surface. By forming a fully coherent interface with the STO substrate and a semi-coherent interface with the strain-free epitaxial VO₂(B) film above, the interfacial bi-layer enables the epitaxial connection of the two materials despite their large symmetry and lattice mismatch.

Epitaxial synthesis of complex oxides has stimulated considerable interest in creating novel functionalities and physical properties, where various means are used to control the close interactions among the order parameters, including lattice, spin, charge, and orbital^{1–4}. Heterostructures of oxide materials have also played an important role in discovering novel phenomena as they can produce well-defined interfaces to couple electronic and magnetic ground states, structure, lattice, crystallographic symmetry, etc. Most studies on the epitaxial growth of complex oxides have focused on isostructural materials, e.g. perovskites on perovskites. While many binary oxides, such as TiO₂ and VO₂, also offer intriguing physical properties^{5–11}, only a few substrates are available with similar structures (lattice parameters and crystal symmetry) for epitaxy thereon. Thus, gaining fundamental insight into the epitaxial growth of binary oxide thin films on lattice and symmetry mismatched substrates is of vital importance for exploring their unprecedented potential^{12–14}.

Recently, high quality VO₂ polymorphs were successfully stabilized as epitaxial thin films using pulsed laser epitaxy (PLE) on perovskite substrates, such as SrTiO₃^{15–17}. Among VO₂ polymorphs¹⁷, bronze-phase VO₂(B) has a monoclinic structure (with C2/m symmetry) whose lattice constants are $a = 12.03$, $b = 3.69$, $c = 6.42$ Å, and $\beta = 106.6^\circ$ ¹⁸, whereas SrTiO₃ (with Pm3m symmetry) has a cubic structure with the lattice constant of 3.905 Å. Note that while many previous studies focused on rhombohedral (R) and monoclinic (M1) phase VO₂, recent studies in developing advanced energy storage found VO₂(B) to be a promising cathode material for Li ion batteries^{19–21}.

In oxide epitaxy, the important role of octahedral connectivity has been well established in perovskite-based oxide heterostructures^{22–24}. Previous studies for heterostructures with a large symmetry mismatch observed the formation of a thin interlayer between the film and substrate induced by either phase transition^{25–30} or phase separation^{31–33}. Moreover, incorporation of such an interfacial buffer layer seems to be critical, enabling the epitaxial growth between large-symmetry-mismatch materials^{34–38}. Interestingly, a previous study based on a STEM observation reported the formation of an imperfect structure at a VO₂(B)/SrTiO₃ interface¹⁶. However, details about the interface structure have not been explored.

In this work, we report how two very dissimilar materials can form an epitaxial heterostructure by aberration-corrected scanning transmission electron microscopy (STEM) imaging and electron energy-loss spectroscopy (EELS). We have found an interfacial bi-layer at the VO₂(B)/STO interface that enables epitaxial growth of a structurally complex, low symmetry film on a high symmetry substrate. It is rather surprising that VO₂(B) films with corner- and edge-sharing oxygen octahedra (see Fig. 1a and b) can be epitaxially grown on STO with corner-sharing octahedra, despite the different oxygen networks and the large biaxial lattice mismatch.

Results and Discussion

High quality VO₂(B) epitaxial films were grown on (001)-oriented STO by PLE under well-optimized growth conditions. The details on the epitaxial growth and crystal quality as well as associated physical properties can

Figure 1. Atomic structure of $\text{VO}_2(\text{B})$. (a,b) Schematics and (c,d) corresponding cross-sectional HAADF images of $\text{VO}_2(\text{B})$ seen along (a,c) the $[100]$ and (b,d) $[010]$ directions. The hexagon in (d) indicates the large open channel in $\text{VO}_2(\text{B})$ useful for ionic conduction.

Figure 2. Microstructure of the $\text{VO}_2(\text{B})/\text{STO}$ interface. HAADF images show two growth twins orthogonally oriented along (a) the $[100]_{\text{VO}_2(\text{B})}$ and (b) $[010]_{\text{VO}_2(\text{B})}$ directions with respect to the $[100]_{\text{STO}}$ direction. (c) LAADF image taken from the image in (b), showing an extra intensity from the interfacial layer (IL) associated with increased electron beam dechanneling and, thus, scattering of electrons due to increased atomic disorder.

be found elsewhere¹⁷. Figure 1 shows atomic structure projections and corresponding cross-sectional high-angle annular dark-field (HAADF) images taken along the $[100]_{\text{VO}_2(\text{B})}$ and $[010]_{\text{VO}_2(\text{B})}$ directions of $\text{VO}_2(\text{B})$. In the Z-contrast HAADF images, the cation columns containing Ti ($Z = 22$), V ($Z = 23$), and Sr ($Z = 38$) are seen with intensities strongly dependent on their atomic number, while columns containing only light O ($Z = 8$) atoms are hardly visible. The image shown in Figure 1d provides the reason why $\text{VO}_2(\text{B})$ is of particular interest for energy storage as the atomic structure seen from the $[010]_{\text{VO}_2(\text{B})}$ direction features an open framework that offers a good ionic diffusion pathway. The structural projection along $[010]_{\text{VO}_2(\text{B})}$ also reveals the clear symmetry mismatch between the film and substrate. Thus, we chose this orientation for the majority of the STEM investigations.

Figures 2a and b show cross-sectional HAADF images of an epitaxial $\text{VO}_2(\text{B})$ film grown on a STO substrate. The images were taken along the $[100]_{\text{STO}}$ direction. As shown in Figures 2a and b, the film is found to contain at least two domains aligned parallel to the $[100]_{\text{VO}_2(\text{B})}$ and $[010]_{\text{VO}_2(\text{B})}$ directions, i.e. orthogonally positioned with respect to the $[100]$ direction of the STO substrate. In fact, the film contains two additional domains that are rotated 180 degrees about the surface normal from those imaged in Fig. 2. A thin (typically ~ 2 nm thick) interfacial layer (IL) can be seen between the $\text{VO}_2(\text{B})$ film and the STO substrate. Based on fast-Fourier transformation (FFT) analysis, an array of misfit dislocations has formed between the IL and the structurally relaxed $\text{VO}_2(\text{B})$ film (as indicated in Fig. 2a and b, and in the corresponding FFT images in Figure S1 in Supporting Information). The interface between the STO substrate and the IL appears to be fully coherent. As shown in Figure 2a and b, the average spacing between dislocations observed along the $[100]_{\text{VO}_2(\text{B})}$ direction is 3.6 ± 0.9 nm, while it is 7.9 ± 1.1 nm when seen along the $[010]_{\text{VO}_2(\text{B})}$ direction. These spacings are in good agreement with calculated values of ~ 3.5 nm and ~ 7.2 nm obtained using the lattice mismatch of $+5.5\%$ for the $[100]_{\text{VO}_2(\text{B})} \parallel [100]_{\text{STO}}$

Figure 3. High-resolution observation of interfacial layer (IL). (a) HAADF image showing that the IL consists of nanodomains, e.g. I and I'. (b,c) Magnified HAADF images taken from nanodomains I and I' marked by the dashed rectangles in a) showing in greater detail the local atom arrangements. (d,e) FFT electron diffraction patterns obtained from the VO₂(B) film and the IL (nanodomain-I), respectively. The red and black arrows between (b,c) indicate extra atom planes formed at the upper and lower sides of IL, respectively.

projection and -2.7% for the orthogonal $[010]\text{VO}_2(\text{B})||[100]\text{STO}$ projection. This result reveals unambiguously that the large bi-axial lattice mismatch between the film and substrate is accommodated by the creation of dislocations at the VO₂(B)/TL interface, i.e. strain-free VO₂(B) epitaxial films are obtained.

Figure 2c shows a low-angle annular dark-field (LAADF) image taken from the sample seen along the $[010]_{\text{VO}_2(\text{B})}/[100]_{\text{STO}}$ direction. The LAADF image highlights the interlayer, which is substantially brighter than the film or the substrate. This brighter contrast in a LAADF image indicates that the IL has a higher level of structural disorder, which leads to the electron dechannelling of the incident beam^{39–41}. Based on a geometric phase analysis (GPA), it is also seen that the VO₂ in the IL undergoes a significant lattice expansion along the film surface normal as compared to the VO₂(B) film (see Figure S2 in Supporting Information). This result is consistent with the rather large in-plane compression (-5.5%) of the VO₂(B) film in the $[100]_{\text{VO}_2(\text{B})}/[100]_{\text{STO}}$ projection that will cause the observed out-of-plane expansion.

Figure 3a shows a HAADF image of the IL taken along the $[010]_{\text{VO}_2(\text{B})}$ direction. While there is a region of the IL (Fig. 3b) that clearly duplicates the projected structure of the relaxed VO₂(B) film above it (except that it is rotated 180 degrees about the surface normal), most of this layer (and its FFT, Fig. 3d,e) looks to be a superposition of $[100]$, $[-100]$, $[010]$, and $[0-10]$ projections of epitaxially strained VO₂(B). The other important feature of the IL is the extra atomic layer between the STO and VO₂(B) indicated with a black arrow in Fig. 3b and c. The atomic layer shows a periodic, but different arrangement of B-site atoms than that of the TiO₂-terminated STO surface. The HAADF images show the out-of-plane lattice spacing between the topmost TiO₂ layer of STO and the extra (Ti,V)-O layer to be $2.4 \pm 0.1 \text{ \AA}$, which is significantly larger than the $1.9 \text{ \AA}$ (001) plane spacing in STO. The intensity variations indicate that, in this $[100]_{\text{STO}}$ projection, the extra layer contains additional (Ti,V) columns with roughly 1/2 the B-site density of its neighboring atom columns.

Spatially resolved STEM-EELS data from the interfacial region is presented in Fig. 4. Figure 4a and b respectively show element maps using the Ti- $L_{2,3}$ and V- $L_{2,3}$ signals taken from the same interfacial region shown in Fig. 4c. The V- $L_{2,3}$ signal in Fig. 4a shows a chemically abrupt interface between the film and STO substrate.

Figure 4. Layer-by-layer EELS analysis. Elemental maps for (a) $V-L_{2,3}$ and (b) $Ti-L_{2,3}$ signals obtained from the interface region shown in (c). (d) Background-subtracted $Ti-L_{2,3}$, $V-L_{2,3}$, and O-K spectra obtained across the interface. The EELS spectra numbered 1 through 9 are obtained from the local atomic planes indicated in (c). EELS profile intensity is normalized using the O-K edge beyond the ionization transitions to discrete states.

On the other hand, the $Ti-L_{2,3}$ signal is seen to extend into the IL. Figure 4d shows background-subtracted $Ti-L$, $V-L$ and O-K EELS profiles obtained layer-by-layer across the IL. Standard spectra obtained from single-crystalline $VO_2(B)$ (V^{4+}) and V_2O_3 (V^{3+}) thin films are also included for comparison. The peak position of $V-L_{2,3}$ edges are seen to remain fixed indicating little to no change in the valence state of V in the IL and the $VO_2(B)$ film.

The $Ti-L_{2,3}$ EELS fine structure obtained from the extra (Ti,V)-O layer on the STO substrate surface shows broadened L_3 and L_2 edges, as well as a shift of the e_g peaks toward lower energy-loss (see Fig. 4d). The observed electronic state and atomic structure of this extra layer are in good agreement with previous theoretical simulations⁴² and STEM observations⁴³ of a $c(4 \times 2)$ reconstructed STO (001) surface composed of a double-layer TiO_2 . The topmost layer of this reconstructed surface was predicted to contain clustered quartets of edge-sharing square-pyramidal TiO_5 ^{42,43}. The extra (Ti,V)-O layer on TiO_2 -terminated STO can introduce edge sharing oxygen containing units, which are more consistent with the $VO_2(B)$ structure. To our knowledge, the formation of such an interface bi-layer can not be explained by any existing growth model that involves either phase transition^{25–30} or phase separation^{31–33} at film/substrate interfaces to accommodate inter-phase structural discontinuities.

The observed results reveal unambiguously, at the initial growth stage, the formation of an interfacial layer composed of $VO_2(B)$ nanodomains that enable the epitaxy of $VO_2(B)$ on STO. This epitaxy with a large symmetry mismatch involves a structural reconstruction process at the substrate surface to facilitate the symmetry transition between the two distinct component structures. The $VO_2(B)$ nanodomains form a fully coherent interface with the STO substrate and are subject to considerable lattice strain. Once the strain energy in the $VO_2(B)$ nanodomains exceeds a critical level, misfit dislocations are introduced, followed by the growth of fully relaxed $VO_2(B)$. The much larger domain size in the relatively strain-free film is an expected result of

increased adatom mobility on the relaxed surface. Formation of the interfacial VO₂(B) nanodomains indicates a nanoscale self-templating process that enables the epitaxy of strain-free VO₂(B) films on STO substrates. Therefore, the results not only enable novel insights into atomic mechanism of complex heterostructure interface at an atomic scale, but also shed light on the epitaxial design of two materials with large symmetry and lattice mismatch.

Methods

Epitaxial synthesis. VO₂(B) epitaxial films were deposited on (001) SrTiO₃ substrates by pulsed laser epitaxy. A sintered ceramic VO₂ target was ablated with a KrF excimer laser ($\lambda = 248$ nm) at a repetition rate of 5 Hz and laser fluence of 1 J·cm⁻². The optimized substrate temperature and oxygen pressure to grow high quality thin films were 500 °C and 20 mTorr, respectively, and the samples were *in-situ* post-annealed in 1 atm of O₂ for 1 hour at the growth temperature to ensure the oxygen stoichiometry. Detailed information on the synthesis of single-crystalline VO₂(B) (V⁴⁺) and V₂O₃ (V³⁺) thin films utilized for EELS analysis can be found elsewhere¹⁴.

Scanning Transmission Electron Microscopy (STEM). Cross-sectional specimens oriented along the [100] STO direction for STEM analysis were prepared using ion milling after mechanical thinning and precision polishing (using water-free abrasive). High-angle annular dark-field (HAADF) and low-angle annular dark-field (LAADF) imaging and electron-energy loss spectroscopy (EELS) analysis were carried out in Nion UltraSTEM200 operated at 200 keV. The microscope is equipped with a cold field-emission gun and a corrector of third- and fifth-order aberrations for sub-angstrom resolution. Inner/outer detector angles of 78/240 mrad and 30/63 mrad were used for HAADF and LAADF imaging, respectively. The convergence semi-angle for the electron probe was set to 30 mrad.
