Two-dimensional (2D) transition-metal dichalcogenides (TMDs) exhibit intriguing properties for both fundamental research and potential application in fields ranging from electronic devices to catalysis. Based on first-principles calculations, we proposed a stable form of palladium diselenide (PdSe_2) monolayer that can be synthesized by selenizing Pd(111) surface. It has a moderate band gap of about 1.10 eV, a small in-plane stiffness, and electron mobility larger than that of monolayer black phosphorus by more than one order. Additionally, tensile strain can modulate the band gap of PdSe_2 monolayer and consequently enhance the infrared light adsorption ability. These interesting properties are quite promising for application in electronic and optoelectronic devices.

Two-dimensional (2D) transition-metal dichalcogenides (TMDs) represent a new family of 2D materials beyond graphene. They have a general formula of MX_2 where M is a transition metal from group 4–10 and X is a chalcogen (S, Se, or Te). In contrast to graphene and their bulk materials, some 2D-TMDs are semiconducting with a sizable band gap, partially due to quantum-confinement effects. So far, theoretical and experimental efforts have been mainly focused on semiconducting 2D-TMDs with $\text{M} = \text{Mo}$ and W^{1-4} , due to potential applications in terahertz switch⁵, lasers and LEDs⁶, ambipolar ionic liquid gated field-effect transistor⁷, photo detectors¹, and so on⁸. In a recent work⁹, PtSe_2 monolayer was synthesized via a single step of direct selenization of a Pt(111) substrate and demonstrated to have potential application as valleytronics and photocatalyst.

Beside platinum, palladium (Pd) can also form binary compounds with Se with different stoichiometries and crystal structures, such as trigonal $\alpha\text{-Pd}_4\text{Se}$, tetragonal PdSe , cubic $\text{Pd}_{17}\text{Se}_{15}$, monoclinic Pd_7Se_2 , and orthorhombic PdSe_2 ¹⁰. Under ambient conditions, PdSe_2 crystal appears in an orthorhombic structure with a space group of Pbcu similar to the case of PdS_2 ^{11,12}. Using first-principles calculations, Sun *et al.*, proposed a PdSe_2 monolayer with semiconducting nature and high Seebeck coefficients¹¹. So far, PdSe_2 monolayer has not been achieved experimentally, partially due to the strong layer binding energy ~ 190 meV/atom in orthorhombic PdSe_2 bulk crystal which makes the exfoliation of PdSe_2 monolayer difficult. However, the recently success in the synthesis of PtSe_2 monolayer on Pt(111) substrate via selenization opens an avenue towards this goal.

In this manuscript, we proposed a novel stable configuration of PdSe_2 monolayer that can be synthesized by selenizing Pd(111) surface, as shown in Fig. 1(a). Our first-principles calculations indicate that it is energetically comparable to the Pbcu phase¹¹. Phonon spectrum analysis confirms its dynamics stability. This PdSe_2 monolayer has an indirect-band-gap of about 1.10 eV, suitable for application in infrared light region. It also has high electron mobility of about $9800\text{--}42000$ $\text{cm}^2\text{V}^{-1}\text{s}^{-1}$ which is larger than that in monolayer black phosphorus by more than one order. The in-plane stiffness of 54 J/m² is only half of MoS_2 , allowing a large tensile strain up to 35%. Additionally, tensile strain can significantly reduce the band gap and consequently enhance the infrared light adsorption ability. These interesting properties are quite promising for application in electronic and optoelectronic devices.

Results and Discussion

Atomic structure and stability. The atomic structure of a freestanding PdSe_2 monolayer with a P-3M1 space group is similar with that of PdSe_2 monolayer grown on the Pd(111) surface, as shown in Fig. 1(a). Each Pd atom bonds to six Se atoms and each Se atom is coordinated by three Pd atoms. All the Pd atoms are on a same

plane sandwiched by two Se planes. The thickness of the freestanding PdSe₂ monolayer measured from the distance between the two Se planes is 2.631 Å. The Pd-Se bond length is about 2.528 Å. The optimized lattice constant of the hexagonal lattice is 3.739 Å, quite close to that of the PtSe₂ monolayer, 3.7 Å⁹. Notably, a 3 × 3 PdSe₂ monolayer (11.217 Å) matches well with the 4 × 4 Pd(111) surface (11.186 Å), which implies high plausibility of growing PdSe₂ monolayer on Pd(111) surface via selenization. This allows us to build a PdSe₂/Pd heterostructure by placing a 3 × 3 PdSe₂ on Pd(111) surface without considering the small lattice mismatch (~0.3%). Compared with freestanding monolayer, the buckling of the supported PdSe₂ increases to 2.710 Å and the bond length vary from 2.51 Å to 2.61 Å with an average of 2.55 Å, due to the substrate effect. The distance between PdSe₂ monolayer and substrate is about 2.16 Å, and the binding energy between them is -1.04 eV per PdSe₂ unit. The PdSe₂-Pd(111) interaction is much stronger than the van der Waals (VDW) interaction in graphite (~-36 meV/atom), making the exfoliation of PdSe₂ from the Pd substrate difficult.

It is noteworthy that the lattice structure of hexagonal PtSe₂ monolayer differs significantly from that cut from orthorhombic PdSe₂ crystal¹¹. The latter case has orthorhombic symmetry with four-coordinated Pt atoms and two-coordinated Se atoms, and is slightly stable than the hexagonal structure by about 26 meV/atom. However, the hexagonal PdSe₂ monolayer matches well with the Pd(111) surface in both symmetry and lattice constant along with a negative binding energy (-1.04 eV per PdSe₂ unit) and thus has high plausibility on the Pd(111) surface as the surface is selenized⁹.

To confirm the dynamic stability of the PdSe₂ monolayer, we calculated the phonon spectrum using a finite displacement method implemented the Phonopy code interfaced the VASP code^{13,14}. It was found that the phonon spectrum is free from imaginary frequency modes, as shown in Fig. 1(b), suggesting the dynamic stability of the PdSe₂ monolayer. Additionally, there is a small energy gap between the acoustic and optical branches in the phonon spectrum. Such an energy gap can protect the vibration of acoustic modes from being interrupted by optical phonon¹⁵⁻¹⁷, which leads to the resonators with higher quality factor than the graphene resonators¹⁸.

Mechanical properties. Strain is not evitable as a monolayer is grown on a substrate. We therefore investigated the mechanical properties PdSe₂ monolayer from first-principles. To obtain the elastic modulus in harmonic range, we employed a rectangular supercell and applied strains along x- and y-direction, as shown in Fig. 1(a). The energy (E_s) dependence of strains is illustrated in Fig. 1(c). The data is fitted to a two-dimensional

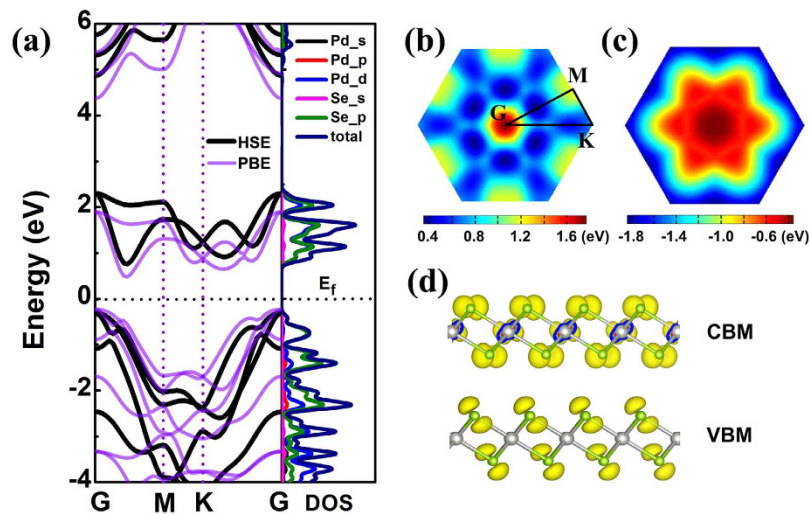

Figure 2. (a) Bands structures of PdSe₂ monolayer along the high symmetric points in the BZ (right) and orbital-resolved electron density of states (left). The energy at the Fermi level is set to zero. The black lines and purple lines represent the data obtained from HSE and PBE functionals, respectively. M (1/2, 0, 0), G (0, 0, 0) and K (1/3, 1/3, 0) represent high symmetric points in the reciprocal space. The momentum-dependent energy distribution in BZ for (b) the lowest unoccupied band and (c) the highest occupied band. (d) Electron density profiles of the Kohn-Sham wavefunctions for CBM and VBM.

polynomial expressed by $E_s = a_1\varepsilon_x^2 + a_2\varepsilon_y^2 + a_3\varepsilon_x\varepsilon_y$, where ε_x and ε_y represent the strains applied along x- and y-direction, respectively. The total energy of system at the equilibrium state was set to zero. It was found that the two parameters a_1 and a_2 are almost identical due to the isotropy in the honeycomb symmetry¹⁹. The poisson's ratio (ν) and in-plane stiffness (C) can be obtained as $\nu = a_3/a_1$ and $C = 1/A_0((2a_1 - a_3^2)/(2a_1)^2)$, where A_0 is the equilibrium area of the structure. The calculated poisson's ratio (0.29) is close to those of MoS₂ (0.25) and silicene (0.30) but larger than that of graphene (0.16). The in-plane stiffness of PdSe₂ monolayer, 54 J/m², is much smaller than those of MoS₂ (123 J/m²) and graphene (335 J/m²)^{19,21}, suggesting that PdSe₂ monolayer is softer than both graphene and MoS₂ monolayer.

The softness of PdSe₂ monolayer was also confirmed by the energetic and structural evolution as a function of biaxial strain. Figure 1(d) gives the energy increase of PdSe₂ monolayer as the biaxial strain varies from -9% (compression) up to 35%. It is interesting to see that energy varies continuously without abrupt decrease, indicating that no Pd-Se bonds are broken in this region. As the tensile strain exceeds 35%, energy decreases drastically and irreversible structure modification along with Pd-Se bond breakage takes place. The two energy local minima at $\varepsilon = 0$ and 20.4% correspond to the equilibrium state and a metal-stable state of PdSe₂ monolayer. The later configuration has the Pd-Se bond length of 2.639 Å, slightly longer than that of the equilibrium state by about 4.4%, but the thickness is greatly reduced to 0.918 Å compared to the equilibrium state value 2.631 Å. The meta-stable state represents a low-buckled configuration of PdSe₂ monolayer under high tensile strain. Similar results have also been reported for silicene, but the critical tensile strain in PdSe₂ monolayer is much larger than that in silicene²¹.

Electronic properties. We then calculated the electronic structure of PdSe₂ monolayer from first-principles. We employed the PBE functional and Heyd-Scuseria-Ernzerhof (HSE) screened Coulomb hybrid density functional²² in the framework of DFT. The band structure and electronic density of states (DOS) near the Fermi level are illustrated in Fig. 2(a). Both functionals gave the semiconducting nature of PdSe₂ monolayer with an indirect band gap, similar to the case of orthorhombic PdSe₂¹¹. The valence band maximum (VBM) resides at the Γ (0, 0, 0) point while the conduction band minimum (CBM) locates in between Γ (0, 0, 0) and M (0.5, 0, 0). Six valleys are therefore found in the whole Brillouin zone as shown in Fig. 2(b), which gives opportunities to valley devices. The PBE functional underestimated the band gap value (0.7 eV) compared with HSE functional (1.10 eV). The band gap of PdSe₂ monolayer is slightly smaller than that of PtSe₂ monolayer (1.2 eV)⁹ and orthorhombic PdSe₂ (1.43 eV)¹¹ and suitable for adsorbing infrared light. From the orbital-resolved electron density of states shown in Fig. 2(a), we can see that the VBM is mainly contributed by the 4p orbitals of Se atoms, while the CBM comes mainly from the 4d orbitals of Pd and 4p orbitals of Se. This is consistent with the features of the Kohn-Sham wavefunctions of the VBM and CBM plotted in Fig. 2(d). Considering Pd is a heavy element, we also took the spin-orbit coupling (SOC) effect into account in electronic structure calculations. It was found that the energy degeneracy at some highly-symmetric points in BZ is lifted due to SOC (Fig. S2 in Supplementary Information). Both the valence and conduction bands are shifted downward and the global indirect band gap is decreased by about 0.2 eV. The reduced band gap would lead to red shift of optical adsorption peaks and thus facilitate the adsorption of infrared light.

When PdSe₂ monolayer is grown on Pd(111) substrate, the energy bands of semiconducting PdSe₂ and metallic Pd substrate mix together. Slight electron redistribution takes place in PdSe₂ monolayer. About 0.05 electrons

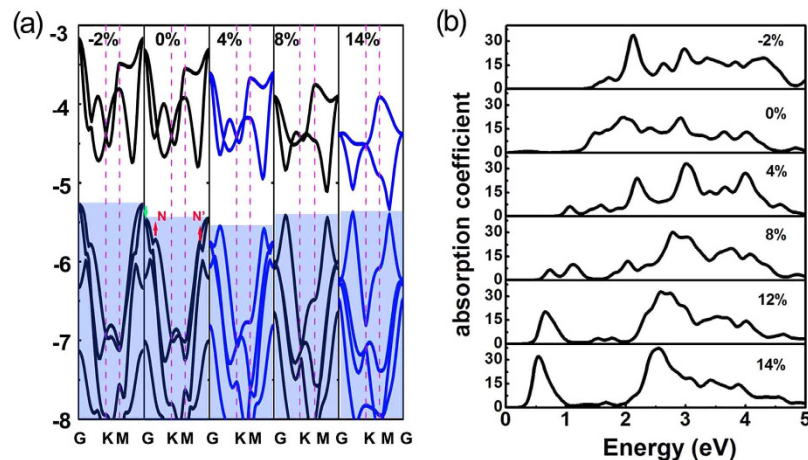

Figure 3. (a) The electronic band structures of PdSe₂ monolayer under different strains obtained from PBE functional. The vacuum level is set to 0 eV. per Se atom transfer from upper Se layer to down Se layer, while the electron transfer from PdSe₂ monolayer to substrate is almost negligible ($\sim 0.007 |e|$ per PdSe₂ unit). This slightly reduces the workfunction of PdSe₂ to 5.20 eV compared with that of freestanding PdSe₂ monolayer (5.40 eV). We also calculated the electronic structures of PdSe₂ multilayers built by stacking PdSe₂ monolayers with different patterns. For the PdSe₂ bilayer, AA stacking pattern is energetically more favorable than AB pattern (Supplementary Information). The interlayer interaction greatly reduces the band gap of 2D PdSe₂. The band gap of the PdSe₂ bilayer with AB pattern is only 0.33 eV (PBE), while the energetically preferred AA pattern becomes metallic.

We also calculated the electron mobility of PdSe₂ monolayer using the phonon-limited scattering model^{23,24}. In the method, the electron mobility can be evaluated using the expression^{24–26}, $\mu_e = e\hbar C_{2D}/(k_B T m_e m_a (E_l)^2)$; where e is the electron charge, \hbar is Planck's constant divided by 2π , k_B is Boltzmann's constant and T is the temperature. m_e is effective mass of electron in the transport direction (either m_x or m_y along the x and y direction, respectively) and m_a is the averaged effective mass of that along x and y direction determined by $m_a = \sqrt{m_x^* m_y^*}$. Deformation potential constant of CBM (E_l) for electrons along the transport direction is defined by $E_l = \Delta V/(\Delta l/l_0)$, ΔV is the energy change of CBM, l_0 is the lattice constant in the transport direction and Δl is the change of l_0 . The elastic modulus C_{2D} of the longitudinal strain in the propagation directions of the longitudinal acoustic wave is derived from $(E - E_0)/S_0 = C(\Delta l/l_0)^2/2$; where E is the total energy and S_0 is the lattice area at equilibrium for 2D system. The electron mobilities along x- and y-direction are $9800 \text{ cm}^2 \text{ v}^{-1} \text{ s}^{-1}$ and $42000 \text{ cm}^2 \text{ v}^{-1} \text{ s}^{-1}$ at 300 K, respectively. These values are much higher than that in monolayer black phosphorus by more than one order of magnitudes. Such high electron mobility is quite promising for improving the photocatalytic activity of PdSe₂ monolayer, because the photo-generated electrons can be easily transferred⁹.

The electronic structure modification of PdSe₂ monolayer in response to tensile strain was then investigated. With the increase of tensile strain, the band gap of PdSe₂ monolayer decreases and comes to close as the tensile is larger than 14%. More interestingly, compressive strain also reduces the band gap of PdSe₂ monolayer. To reveal the origins of the strain-induced band gap modulation, we plotted the band structures of PdSe₂ monolayer under difference strains in Fig. 3(a). From this figure, we can see that under a tensile strain, the CBM move downwards while the VBM varies slightly, reducing the band gap. This may be related to the enhancement of the Se_{4p} and Pd_{4d} interaction due to the shorten distance between the Se plane and Pd plane. Under a compressive strain, however, the VBM is sensitive to strain and shifts upwards, leading to band gap reduction. Besides, it is interesting to see that tensile strain decreases the energy of the G points (illustrated by green arrow in Fig. 3(a)), and lifts the energies of the N and N' points (illustrated by red arrow in Fig. 3(a)). As the tensile strain is larger than 4%, the energy difference between the N and N' points becomes very small, making the PdSe₂ a quasi-direct band semiconductor.

Optical adsorption. The strain-induced band gap reduction affects the optoelectronic properties of PdSe₂ monolayer. We calculated the imaginary part of complex dielectric function using the expression:

$$\epsilon''_{\alpha\beta(\omega)} = \frac{4\pi^2 e^2}{\Omega} \times \lim_{q \rightarrow 0} \frac{1}{q^2} \sum_{c,v,k} 2\omega_k \delta(\epsilon_{ck} - \epsilon_{vk} - \omega) \times \langle \mu_{ck+eq} | \mu_{vk} \rangle \langle \mu_{ck+eq} | \mu_{vk} \rangle^* .$$

The indices c and v refer to conduction and valence band states respectively. u_{ck} is the cell periodic part of the orbitals at the k -point \mathbf{k} . ω is the frequency of the incident photon. The real part of the dielectric function $\epsilon'_{\alpha\beta(\omega)}$ is obtained from the imaginary part with the Kramers-Kroning relations. The optical absorption coefficient is given

by $I(\omega) = \sqrt{2}\omega[\sqrt{\epsilon'(\omega)^2 + \epsilon''(\omega)^2} - \epsilon'(\omega)]^{\frac{1}{2}}$; where ϵ' and ϵ'' is the real and imaginary part of complex dielectric function. The optical absorption coefficient $I(\omega)$ calculated using HSE functional is plotted in Fig. 3(b). At equilibrium state, the adsorption peaks locate in the visible light and ultraviolet light region. A small compression has little affect on the adsorption properties. When a tensile strain is applied to PdSe₂ monolayer, adsorption peaks come to appear in the low energy region, due to the band gap reduction. Meanwhile, the adsorption to visible light is partially screened. For example, under the tensile strains larger than 12%, the adsorption coefficients are almost zero in the energy region from 1.0–2.0 eV. These fascinating properties are quite promising for infrared detectors where the screening of visible light adsorption is needed.

Conclusion

In summary, based on first-principles calculations, we proposed a stable form of palladium diselenide (PdSe₂) monolayer that may be synthesized by selenizing Pd(111) surface. The PdSe₂ monolayer possesses a moderate band gap of about 1.10 eV and high electron mobilities of about 9800–42000 cm²v⁻¹s⁻¹, suitable for the electronic and optoelectronic devices working at infrared light region. The band gap of PdSe₂ monolayer can be modulated by applying tensile strains. With the increase of tensile strain, the band gap decreases and comes to close as the tensile strain is larger than 14%. Consequently, the light adsorption ability of the PdSe₂ monolayer in infrared light region is greatly enhanced. These findings are quite promising for application in electronic and optoelectronic devices.

Methods

Our first-principles calculations were performed within density-functional theory (DFT) using the Vienna ab initio simulation package known as the VASP code^{27–29}. The projector augmented wave method (PAW)^{30,31} was used to describe the electronic-ion interaction. The energy cutoff of the plane waves was set to 450 eV with an energy precision of 10⁻⁵ eV. The electron exchange–correlation function was treated using a generalized gradient approximation (GGA) in the form proposed by Perdew, Burke, and Ernzerhof (PBE)³². The Monkhorst-Pack *k*-point meshes³³ for the Brillouin zone (BZ) sampling used in structural optimization and electronic structure calculations are 8 × 8 × 1 and 15 × 15 × 1, respectively. The primitive cell contains one Pd atom and two Se atoms which is periodically repeated along the x- and y-directions. A vacuum region up to 15 Å was applied along the z-direction to exclude the interaction between adjacent images. Both atomic positions and lattice vectors were fully optimized using the conjugate gradient (CG) algorithm until the maximum atomic forces were less than 0.0005 eV/Å. The lattice constants of the orthorhombic PdSe₂ crystal (a = 5.752 Å, b = 5.926 Å) obtained from our calculations agree well with the experimental data (a = 5.746 Å, b = 5.868 Å)¹², confirming the validity of this strategy.
