Insight into the Role of Surface Wettability in Electrocatalytic Hydrogen Evolution Reactions Using Light-Sensitive Nanotubular TiO₂ Supported Pt Electrodes

Chenhui Meng¹, Bing Wang¹, Ziyue Gao¹, Zhaoyue Liu¹, Qianqian Zhang² & Jin Zhai¹

Surface wettability is of importance for electrochemical reactions. Herein, its role in electrochemical hydrogen evolution reactions is investigated using light-sensitive nanotubular TiO₂ supported Pt as hydrogen evolution electrodes (HEEs). The HEEs are fabricated by photocatalytic deposition of Pt particles on TiO₂ nanotubes followed by hydrophobization with vaporized octadecyltrimethoxysilane (OTS) molecules. The surface wettability of HEEs is subsequently regulated *in situ* from hydrophobicity to hydrophilicity by photocatalytic decomposition of OTS molecules using ultraviolet light. It is found that hydrophilic HEEs demonstrate a larger electrochemical active area of Pt and a lower adhesion force to a gas bubble when compared with hydrophobic ones. The former allows more protons to react on the electrode surface at small overpotential so that a larger current is produced. The latter leads to a quick release of hydrogen gas bubbles from the electrode surface at large overpotential, which ensures the contact between catalysts and electrolyte. These two characteristics make hydrophilic HEEs generate a much high current density for HERs. Our results imply that the optimization of surface wettability is of significance for improving the electrocatalytic activity of HEEs.

Hydrogen, as a clean and portable energy carrier, has been attracting worldwide attention because of its possibility to replace fossil fuels in the future^{1,2}. Electrocatalytic water splitting is one of sustainable route to produce hydrogen from water by electricity^{3,4}. In this route, catalytic Pt electrodes are often used as hydrogen evolution electrodes (HEEs) to achieve hydrogen evolution reactions (HERs)^{5,6}. A complete HER in acidic solution involves three procedures of proton migration, proton reduction and hydrogen gas release⁷. The last two procedures occur at solid-liquid (electrode-electrolyte) and solid-gas (electrode-hydrogen) interface respectively, which affect the electrocatalytic activity of HEEs significantly. Therefore, understanding the role of surface properties of HEEs in HERs is of significance for improving their electrocatalytic performances.

Surface wettability, as one of fundamental surface properties of an electrode, shows a significant influence on electrolyte-wetting, redox electron transfer and gas release in electrochemical reactions^{8–11}. For example, a superhydrophobic surface can control the precursor-wetting and guide gold nanoparticles to electrochemically grow along solid-liquid-gas triphase interface⁹. A hydrophilic surface enhances the extracellular electron transfer rate between microbes and electrode¹⁰. In water electrolysis under microgravity, the oxygen evolution is also affected significantly by the wettability of electrode¹¹. However, to the best of our knowledge, how the surface wettability of HEEs affects the HERs has not been investigated systematically.

Recently, lots of progress has been achieved on the wettability regulation of solid surface using responsive materials sensitive to external stimuli^{12–16}, which makes it possible to regulate the surface wettability of HEEs in a wide range. Herein, the surface wettability of HEEs consisting of octadecyltrimethoxysilane-modified

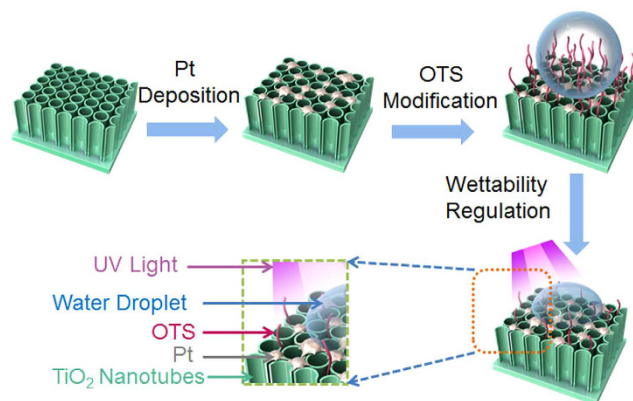

Figure 1. Flow chart for the fabrication and wettability regulation of nanotubular TiO_2 supported Pt electrodes (Pt- TiO_2 -NTs). Pt catalysts were deposited on the surface of anodized TiO_2 nanotubes (TiO_2 -NTs) by photocatalytic reduction, which was followed by hydrophobization with vaporized octadecyltrimethoxysilane (OTS) molecules. The wettability of Pt- TiO_2 -NTs was subsequently regulated *in situ* from hydrophobicity to hydrophilicity using ultraviolet (UV) light.

nanotubular TiO_2 supported Pt electrodes (Pt- TiO_2 -NTs) was regulated *in situ* from hydrophobicity to hydrophilicity using external stimulus of ultraviolet (UV) light and its role in HERs was investigated systematically. It is found that hydrophilic HEEs generate a much higher current density for HERs when compared with hydrophobic ones. We conclude that this high electrocatalytic activity is associated with their large electrochemical active area of Pt and low adhesion force to a gas bubble.

Results and Discussion

Electrochemically anodized TiO_2 nanotubes (TiO_2 -NTs) on Ti metals have been used as a substrate to support electrocatalysts of Pt or MoS_2 for HERs^{17,18}. The significant advantage of TiO_2 -NTs as a substrate is that their photocatalysis can trigger some special reduction reactions, which result in the direct loading of particulate catalysts on the surface of TiO_2 -NTs without the necessity of using additional immobilization procedures. Furthermore, TiO_2 -NTs shows a rough surface, which can be used to fabricate hydrophobic surface via chemical modification^{19–23}. As shown in Fig. 1, the fabrication and wettability regulation of Pt- TiO_2 -NTs involves four steps: (1) formation of anatase TiO_2 -NTs on Ti metals by a combination of electrochemical anodization and high-temperature calcination^{24–28}; (2) deposition of Pt catalysts on TiO_2 -NTs by photocatalytic reduction of chloroplatinic acid under UV illumination²⁹; (3) hydrophobization with vaporized octadecyltrimethoxysilane (OTS) molecules^{19–23}; (4) wettability regulation of OTS-modified Pt- TiO_2 -NTs by photocatalytic decomposition of OTS molecules using UV light^{19,20,22,23}.

As shown in Fig. 2a, the as-prepared TiO_2 -NTs show a clean nanopore surface with a pore inner diameter of ~86 nm and a pore wall of ~11 nm. After photocatalytic deposition of Pt (Fig. 2b), only a small quantity of TiO_2 -NTs is covered by Pt aggregates with a size of ~230 nm. Most of TiO_2 -NTs are not covered by Pt aggregates. The magnified SEM image of TiO_2 -NTs without covering of Pt aggregates (Inset of Fig. 2b) show that Pt nanoparticles with a size of ~10 nm distribute on the perimeter of nozzles of TiO_2 -NTs, which indicates that Pt catalysts distributes throughout the whole surface of TiO_2 -NTs. Our results are consistent with the findings of Herrmann *et al.* that some Pt particles are present as large aggregates after a long-time photocatalytic reaction besides the small Pt nanoparticles³⁰. Element maps and energy dispersive X-ray microanalysis (EDX) patterns are used to further investigate the distribution of Pt catalysts on the surface of TiO_2 -NTs. Figure 2c and d show the element maps and EDX of two specific areas with and without covering of Pt aggregates (area I and II in Fig. 2b respectively). In both areas, the characteristic lines at energy of ~2.05 keV for Pt elements are detected^{31,32}, which indicates that Pt elements distribute throughout the whole surface of TiO_2 -NTs. The area consisting of large aggregates demonstrates a higher Pt content when compared with the one without aggregates, which is evidenced by the strong Pt characteristic lines in Fig. 2c. The composite surface of Pt- TiO_2 -NTs demonstrates one important characteristic that the surface of TiO_2 -NTs is not densely covered by Pt particles. The exposed TiO_2 -NTs surface is necessary for wettability regulation using UV light because photocatalytic oxidation ability is available only on TiO_2 surface.

In order to enable the surface wettability of Pt- TiO_2 -NTs to be sensitive to UV light, OTS molecules were deposited on their surface using chemical vapor deposition method (Fig. 1). After OTS modification, as shown in Fig. 3, the surface of Pt- TiO_2 -NTs is hydrophobic with a water contact angle (CA) of ~139°. This hydrophobicity is ascribed to the synergistic effect of rough nanopore surface and hydrophobic octadecyl carbon chains in OTS molecules^{33–35}. It has been known that the surface hydroxyls of TiO_2 -NTs are important for the silanization reactions because they can form covalent bonds with OTS molecules^{36,37}. However, in order to immobilize silane molecules on the surface of Pt, an anodization process to generate oxide surface with hydroxyls is necessary^{38,39}. Therefore, it is reasonably considered that OTS molecules are difficult to covalently bond to the as-prepared Pt particles (including the large Pt aggregates with a size of ~230 nm and the small Pt nanoparticles with a size of ~10 nm). In order to confirm the distribution of OTS molecules, the silicon EDX patterns of OTS-modified Pt- TiO_2 -NTs after UV illumination for 200 min (Figure S1 in Supplementary information) are measured. It has

Figure 2. (a,b) SEM images of TiO₂-NTs (a) before and (b) after photocatalytic deposition of Pt particles. Only a small quantity of TiO₂-NTs is covered by Pt aggregates with a size of ~230 nm. Inset of b: magnified SEM image of TiO₂-NTs without covering of Pt aggregates. Pt nanoparticles with a size of ~10 nm distribute on the perimeter of nozzles of TiO₂-NTs. (c,d) Element maps and EDX patterns on the specific areas (c) with and (d) without covering of Pt aggregates as shown in b (area I and II). In both areas, the characteristic lines at energy of ~2.05 keV for Pt elements are detected. The area with covering of large aggregates demonstrates a high Pt content.

Figure 3. The evolution of water contact angles (CAs) of OTS modified Pt-TiO₂-NTs following *in situ* UV illumination. Insets: The corresponding water CAs when the UV illumination time is 0, 15, 50 and 200 min. The water CAs are sensitive to light, which can be regulated on demand from ~139° to ~13°.

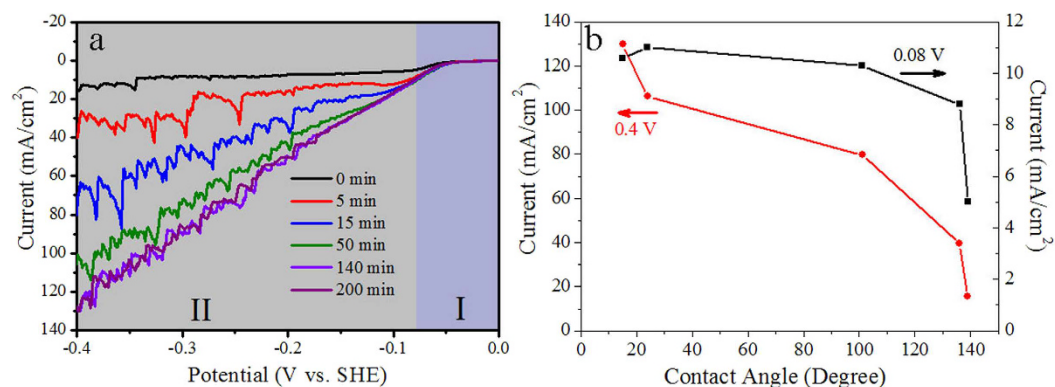

Figure 4. (a) Polarization curves of OTS-modified Pt-TiO₂-NTs after *in situ* UV illumination for 0, 5, 15, 50, 140 and 200 min in 0.5 M H₂SO₄. The polarization curves are divided into two regions of I and II by a potential of -0.08 V. (b) The quantitative correlations between the water contact angles (CAs) of OTS-modified Pt-TiO₂-NTs and the catalytic current density for HERs at an overpotential of 0.08 V and 0.4 V. Following the decrease of water CA by UV illumination, the enhanced degree of current density in region II is much larger than that in region I.

been known that after a photocatalytic reaction the carbon chains of OTS molecules will be decomposed and silicon elements are left⁴⁰. Figure S1 indicate clearly that Si elements mainly distribute on the surface of TiO₂-NTs. However, on the surface of Pt aggregates, the characteristic line of Si element is very weak. Our results indicated that OTS molecules can deposit selectively on TiO₂-NTs. Following *in situ* UV illumination, the water CA can be controlled on demand from $\sim 139^\circ$ to $\sim 13^\circ$, which are determined by the UV illumination time. The decrease in water CA is ascribed to wettability change of TiO₂-NTs, which results from the controllable decomposition of alkyl chains in OTS molecules by the oxidation ability of TiO₂ photocatalysis^{40,41}.

Subsequently, we investigated the role of surface wettability of Pt-TiO₂-NTs in HERs. The wettability was controlled *in situ* by UV illumination time. Figure 4a shows the polarization curves of Pt-TiO₂-NTs with different wettability in 0.5 M H₂SO₄ electrolyte. The quantitative correlations between the water CAs of Pt-TiO₂-NTs and the current density values for HERs at an overpotential of 0.08 V and 0.4 V are summarized in Fig. 4b. The polarization curves are divided into two regions of I and II by a potential of -0.08 V (vs. SHE). For hydrophobic Pt-TiO₂-NTs with a water CA of $\sim 139^\circ$, the characteristics of polarization curve in region I and II are different. In region I with overpotential smaller than 0.08 V, the increase in the overpotential enhances the current density for HERs (Fig. 4a and Figure S2 in Supplementary information). In this region, it is considered that the evolved hydrogen gas can dissolve into the electrolyte because a small current density is not sufficient to supersaturate the electrolyte⁴². Therefore, no hydrogen bubbles form on the surface of Pt-TiO₂-NTs. The current density for HERs is only dependent on the potential. At a typical potential of -0.08 V (vs. SHE), hydrophobic Pt-TiO₂-NTs generate a current density of 5.0 mA/cm². However, in region II with overpotential larger than 0.08 V, the concentration of hydrogen gas in the electrolyte reaches a critical value, the hydrogen gas bubbles nucleate and grow on the surface of electrode⁴², which will occupy the catalytically active sites of Pt for HERs. Therefore, in region II, although the overpotential increases from 0.08 to be 0.4 V (vs. SHE), the current density increases very slowly from 5.0 to 15.6 mA/cm² for hydrogen evolution.

When the water CA of hydrophobic Pt-TiO₂-NTs is lowered by UV illumination, the current density of Pt-TiO₂-NTs in region I increases as shown in Fig. 4b and Fig. S2 in supplementary information. Hydrophilic Pt-TiO₂-NTs with a water CA of $\sim 24^\circ$ obtained by UV illumination for 50 min generate a current density of 11.0 mA/cm² at -0.08 V (vs. SHE), which is almost 2.2 times as much as that (5.0 mA/cm²) of hydrophobic ones with a water CA of $\sim 139^\circ$. Further extending the UV illumination time does not enhance the current density in region I (Fig. 4b). Since no large hydrogen gas bubbles are generated in region I because of the small overpotential, the enhanced current density is ascribed to the increase in the electrochemical active area of Pt (ECA) by a hydrophilic surface. During wettability regulation, the ECA of large Pt aggregates remains almost unchanged because they stay on the surface of TiO₂-NTs and can contact the electrolyte. However, the ECA of the small nanoparticles (~ 10 nm) on the perimeter of nozzles of TiO₂-NTs is related with the surface wettability. For a hydrophobic surface, Pt nanoparticles cannot be wetted by the electrolyte because of the sealed air in the nanotubes, which results in a small ECA. When the surface wettability of Pt-TiO₂-NTs is regulated to be hydrophilic, TiO₂-NTs can be wetted by the electrolyte. Pt nanoparticles on the perimeter of nozzles of TiO₂-NTs then contact the electrolyte and show a large ECA.

The ECA of Pt can be estimated based on the adsorption and desorption of hydrogen as electrochemical adsorbates. The hydrogen adsorption charge is then converted into ECA based on the well-established relationship of $210 \mu\text{C}/\text{cm}^2$ for polycrystalline Pt surfaces^{43,44}. As shown in Fig. 5, hydrophobic Pt-TiO₂-NTs with a water CA of $\sim 139^\circ$ demonstrate a low ECA of $\sim 4.9 \text{ cm}^2$. After UV illumination for 5 and 50 min, two couples of current peaks are observed for hydrogen adsorption and desorption. The calculated ECA of Pt based on hydrogen adsorption is ~ 8.7 and $\sim 9.9 \text{ cm}^2$ respectively. Therefore, hydrophilic Pt-TiO₂-NTs allow more protons to react on the electrode surface, which contributes to the enhancement of current density for HERs in region I of Fig. 4a.

Figure 5. Cyclic voltammogram curves of hydrophobic OTS-modified Pt-TiO₂-NTs in 0.5 M H₂SO₄ after UV illumination for 0, 5 and 50 min. The scan rate is 50 mV/s. The two couples of current peaks are associated with the hydrogen adsorption and desorption. The calculated electrochemical active area based on hydrogen adsorption increases following the increase of UV illumination time.

Figure 6. Formation of hydrogen gas bubbles on the surface of OTS-modified Pt-TiO₂-NTs electrode at -0.4 V (vs. SHE) after UV illumination for (a) 0, (b) 50 and (c) 200 min. The hydrophilicity reduces the size of hydrogen gas bubbles sticking on the electrode surface. The scale bar is 250 μ m.

However, in region II with large overpotential, the current density is enhanced exceptionally by a hydrophilic surface. As shown in Fig. 4b, Hydrophilic Pt-TiO₂-NTs with a water CA of $\sim 15^\circ$ obtained by UV illumination for 140 min generate a current density of 129.8 mA/cm² at -0.4 V (vs. SHE), which is almost nine times as much as that of hydrophobic Pt-TiO₂-NTs with a water CA of $\sim 139^\circ$ (15.6 mA/cm²). The different degree for current enhancement by a hydrophilic surface at small (0.08 V) and large (0.4 V) overpotential indicates that the surface wettability is not the only reason for the high catalytic activity of hydrophilic Pt-TiO₂-NTs. In region II, a lot of hydrogen gas bubbles are generated during HERs because of the large overpotential. Therefore, it is considered that this exceptionally enhanced current density in region II by a hydrophilic surface should be related with its low adhesion force of electrode surface to a gas bubble. In HERs, when the concentration of hydrogen in electrolyte reaches a critical value, hydrogen gas bubbles will nucleate and grow on the electrode surface, which will occupy the catalytically active sites. Once the surface adhesive force cannot sustain the hydrogen gas bubbles, they will detach the electrode surface and releases the occupied active sites for HERs⁴². As shown in Fig. 6a, for hydrophobic Pt-TiO₂-NTs with water CA of $\sim 139^\circ$, when the potential is scanned to be -0.4 V (vs. SHE), a lot of hydrogen gas bubbles with a size larger than ~ 80 μ m adhere on the electrode surface. The video during polarization process demonstrates that the small hydrogen bubbles will merge into a large one, which sticks on the electrode surface strongly (Video S1 in Supplementary information). The smooth polarization curve of Pt-TiO₂-NTs with a water CA of $\sim 139^\circ$ (Fig. 4a) also imply that the hydrogen gas bubble is difficult to leave the surface of hydrophobic electrode. These gas bubbles prevent the contact between catalysts and electrolyte, and consequently reduce the electrocatalytic activity. After the hydrophobic Pt-TiO₂-NTs are illuminated by UV light for 50 min, some large gas bubbles will leave the electrode surface in HERs. The size of the adhered gas bubbles decreases obviously (Fig. 6b), which reduces the occupation area of gas bubbles and increases the catalytic activity. The large current shake in Fig. 4a also implies the detachment of gas bubbles from the electrode surface. The size of adhered bubbles can be further decreased by extending the UV illumination time to be 200 min (Fig. 6c).

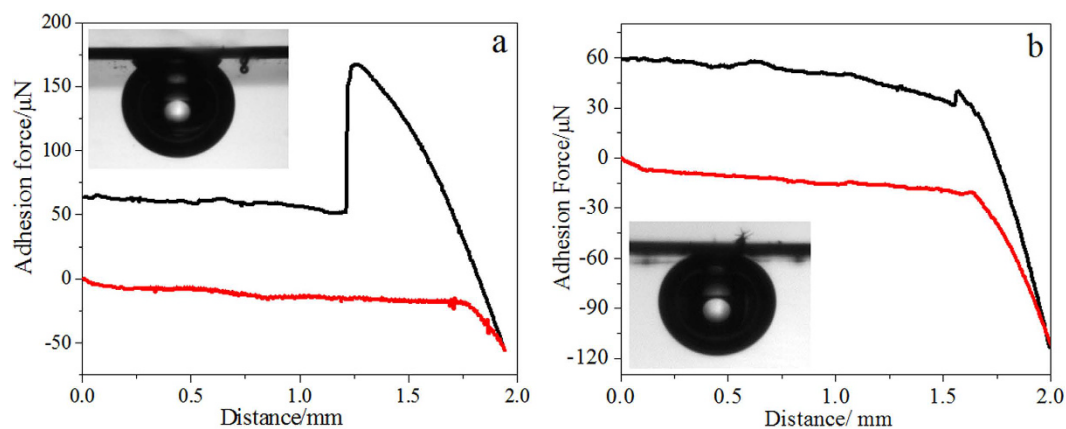

Figure 7. Adhesive force-distance curves when Pt-TiO₂-NTs with a water CA of ~139° (a, hydrophobic) and ~14° (b, hydrophilic) approach to and retract from an external gas bubble. Insets: The corresponding underwater gas CAs. A hydrophilic surface shows a low adhesion force and a high underwater gas CA.

In this case, most of small hydrogen bubbles can leave the electrode surface quickly during hydrogen evolution (Video S2 in Supplementary information), which results in a high electrocatalytic activity^{45–47}.

It has been well-known that the adhesion force of a solid surface to a gas bubble is related with its surface wettability^{48,49}. Herein, a high-sensitivity microelectromechanical balance system is used to measure quantitatively the adhesion force of Pt-TiO₂-NTs with different wettability to a gas bubble in water. Figure 7a shows the adhesive force-distance curves when Pt-TiO₂-NTs with a water CA of ~139° approach to and retract from a gas bubble with a volume of 5 μL. The starting position of Pt-TiO₂-NTs is defined to be zero point of distance. As shown in Fig. 7a, at a distance of ~1.95 mm, Pt-TiO₂-NTs contact the gas bubble. Then, Pt-TiO₂-NTs start to move away from the gas bubble. The balance force between Pt-TiO₂-NTs and gas bubble gradually increases because of the adhesion of gas bubble on the surface of Pt-TiO₂-NTs, which reaches a maximum at a distance of ~1.26 mm. When the gas bubble breaks away from Pt-TiO₂-NTs at the distance of ~1.26 mm, the force between Pt-TiO₂-NTs and gas bubble disappears. The jump at distance of ~1.26 mm represents the adhesive force of Pt-TiO₂-NTs to a gas bubble, which is calculated to be ~116 μN. A gas bubble is easy to adhere onto the surface of hydrophobic Pt-TiO₂-NTs (Video S3 in Supplementary information). This large adhesion force is ascribed to the existence of trapped air pockets in TiO₂-NTs by water. When an external gas bubble approach to the surface area of hydrophobic Pt-TiO₂-NTs, it will coalesce with the air pockets in TiO₂-NTs to form fresh gas-liquid-solid three-phase lines (as evidenced by a relatively low underwater gas CA of ~136° in the inset of Fig. 7a), which results in a large adhesion force⁴⁸. After the hydrophobic Pt-TiO₂-NTs are converted to be hydrophilic by UV illumination, as shown in Fig. 7b, the small jump at a distance of 1.57 mm represents a small adhesive force of ~9 μN because of the complete wetting of TiO₂-NTs by water and no air is trapped. The surface therefore demonstrates a high underwater gas CA of ~157° (inset of Fig. 7b). A gas bubble is very hard to adhere onto the surface of hydrophilic Pt-TiO₂-NTs (Video S4 in Supplementary information). This extremely low adhesion force can drive large hydrogen gas bubbles to leave the electrode surface quickly in HERs which ensures the contact between Pt catalytic active sites and electrolyte, and increases the catalytic activity.

Conclusions

In summary, the role of surface wettability in HERs has been investigated using light-sensitive hydrophobic Pt-TiO₂-NTs as HEEs. The surface wettability of Pt-TiO₂-NTs is facilely regulated *in situ* from hydrophobicity to hydrophilicity using an irradiation of UV light. The measurements of polarization curves indicate that the electrocatalytic activity of Pt-TiO₂-NTs for HERs is enhanced by a hydrophilic surface. At a low overpotential without formation of large hydrogen bubbles, this enhancement of current density mainly results from the increased electrochemical active area. However, at a high overpotential, the exceptionally enhanced current density mainly results from the low adhesion force of a hydrophilic surface for a gas bubble, which can drive large hydrogen gas bubbles to leave the electrode surface quickly and ensures the contact between Pt catalytic and electrolyte. Our present work indicates that the optimization of surface wettability of HEEs is important for the improvement of their electrocatalytic activity for HERs.

Experimental

Fabrication of nanotubular TiO₂ supported Pt electrodes. TiO₂ nanotubes (TiO₂-NTs) on Ti substrate were prepared by an electrochemical anodization at a constant voltage of 20 V for 20 min in 0.5% HF aqueous solution^{20–23}. The anatase crystallization was achieved by annealing as-formed TiO₂-NTs at 450 °C for 3 h. Pt particles were deposited directly on TiO₂-NTs by photocatalytic reduction of chloroplatinic acid (H₂PtCl₆·6H₂O) precursor in H₂O/isopropanol mixed solvent with volume ratio of 9:1²⁹. The photocatalytic reaction time is 50 min. The light source is 365-nm ultraviolet (UV) light from a high-pressure mercury lamp with an irradiance of 5 mW/cm². For convenience, Pt-deposited TiO₂-NTs were denoted as Pt-TiO₂-NTs.

In situ Wettability Regulation of Pt-TiO₂-NTs Using UV Light. In order to enable the surface wettability of Pt-TiO₂-NTs to be sensitive to external UV light, the surface was hydrophobicated with octadecyltrimethoxysilane (OTS, Aldrich) molecules. Pt-TiO₂-NTs were placed in a Teflon-lined stainless autoclave with 100 μg of OTS, which was heated to 130 °C and kept at this temperature for 3 h. Then, the surface wettability of OTS-modified Pt-TiO₂-NTs was regulated *in situ* from hydrophobicity to hydrophilicity gradually using UV illumination^{19,20,22,23}. The strong oxidation ability of TiO₂ photocatalysis under UV illumination decomposed OTS molecules, which resulted in a wettability change.

Evaluation of Electrocatalytic Activity. The electrocatalytic activities of Pt-TiO₂-NTs with different wettability for HERs were evaluated by measuring the polarization curves in 0.5 M H₂SO₄ solution using a three-electrode configuration¹⁷. The polarization potential was supplied by a CHI660D potentiostat (Shanghai Chenhua Apparatus Co., China) with a scanning rate of 5 mV/s. The working electrode is Pt-TiO₂-NTs with a geometric area of 1 cm², and the counter electrode is Pt wire. The electrochemical active area of Pt was calculated by measuring the cyclic voltammogram curves of Pt-TiO₂-NTs electrodes in 0.5 M H₂SO₄ solution using a scan rate of 50 mV/s. An Ag/AgCl electrode in 3.5 M KCl solution was used as a reference electrode. The potential was calibrated to be against standard hydrogen electrode (SHE) based on an equation of φ (V vs. SHE) = φ (V vs. Ag/AgCl) + 0.205 V.

Characterizations. The morphology of Pt-TiO₂-NTs was observed using an environmental scanning electron microscope (FEI Quanta FEG 250) at 10 kV. An OXFORD INCA Energy 250 energy spectrum analyzer linked on JEOL JSM-7500F field-emission scanning electron microscope was used to detect the surface chemical elements. The evolution of hydrogen gas bubbles during HERs was imaged *in situ* by a camera. The water and underwater gas bubble contact angles (CAs) of the electrode were characterized using an OCA20 contact-angle system (Dataphysics, Germany). The adhesive force of the electrode surface to a gas bubble was measured using a high-sensitivity micro-electromechanical balance system (Dataphysics DCAT21, Germany). A gas bubble with a volume of 5 μL was suspended on a metal ring, and then Pt-TiO₂-NTs began to approach to the gas bubble. The starting position of Pt-TiO₂-NTs is defined to be zero point of distance. Once contacted, Pt-TiO₂-NTs started to move away from the gas bubble. The balance force between Pt-TiO₂-NTs and gas bubble would gradually increase, and reach a maximum when the gas bubble just broke away from Pt-TiO₂-NTs. The change of balance force resulting from the detachment of gas bubble from the surface of Pt-TiO₂-NTs was defined as the adhesive force.

Acknowledgements

This work was supported by National Natural Science Foundation of China (21571011) and National Basic Research Program of China (2014CB931803)

Author Contributions

Z.L. and J.Z. designed the project. Z.L. and Q.Z. organized the research. C.M., B.W. and Z.G. performed the experiments. Z.L. and C.M. wrote the manuscript.
