We present the first experimental evidence for metallicity, superconductivity (SC) and the coexistence of charge density waves (CDW) in the quasi-one-dimensional material HfTe_3 . The existence of such phenomena is a typical characteristic of the transition metal chalcogenides however, without the application of hydrostatic pressure/chemical doping, it is rare for a material to exhibit the coexistence of both states. Materials such as HfTe_3 can therefore provide us with a unique insight into the relationship between these multiple ordered states. By improving on the original synthesis conditions, we have successfully synthesised single phase HfTe_3 and confirmed the resultant structure by performing Rietveld refinement. Using low temperature resistivity measurements, we provide the first experimental evidence of SC at ~ 1.4 K as well as a resistive anomaly indicative of a CDW formation at ~ 82 K. By the application of hydrostatic-pressure, the resistivity anomaly shifts to higher temperature. The results show that HfTe_3 is a promising new material to help study the relationship between SC and CDW.

The coexistence of superconductivity (SC) and charge- and/or spin-density waves (CDW and/or SDW) is fundamental to our understanding behind the mechanism of high- T_c SC and is one of the most significant challenges in condensed matter physics¹. CDWs favor low dimensionality² and materials such as the layered/chain-like transition metal di/trichalcogenides (MQ_2/Q_3) (where M = groups IV–VI transition metals and Q = sulfur, selenium and tellurium) have been collectively studied for such phenomena³. Examples include TaS_3 ⁴ and NbS_3 ⁵ which exhibit CDWs and TaSe_3 which becomes a SC below 2.1 K⁶. Studies of SC in the MQ_2/Q_3 family often support a competitive relationship between the SC and CDW states; SC can be induced/enhanced by the suppression of the CDW. This is typically achieved by the application of hydrostatic pressure such as in the case of NbSe_2 ⁷ and NbSe_3 ⁸ or by chemical doping for Na_xTaS_2 ⁹ and Cu_xTiSe_2 ¹⁰. However, it is rare that the materials without chemical/physical modification exhibit the co-existence of both states. ZrTe_3 is a material which shows the coexistence of a CDW at ~ 63 K and filamentary SC at 2 K¹¹ as does NbSe_2 ³. In the case of ZrTe_3 , by the application of pressure, intercalation of Cu¹² and Ni¹³ or the substitution of Se at the Te site¹⁴, the CDW can be suppressed and bulk SC induced at ~ 5 K¹⁵. The electronic structure of ZrTe_3 is unique amongst the MQ_3 family owing to the strong contribution of the Te–Te p_{σ^*} band at the vicinity of the Fermi level¹⁶, therefore the inter-chain interactions affects the electronic structure as well as the physical properties. Similar cross-chain interactions are absent in other members of the MQ_3 family (when M = group IV transition metal and Q = S/Se)¹⁷. Of the MTe_3 materials, HfTe_3 is the only other material expected theoretically^{18,19}. There are no known reports for TiTe_3 nor Nb/TaTe_3 . However, by using the reaction conditions outlined by Brattås *et al.* we found that the successful synthesis of HfTe_3 ^{18,19} was irreproducible. Therefore, although theoretical band structure calculations have predicted HfTe_3 to be metallic^{16,20,21} there is currently no experimental confirmation. As far as the authors are aware, the available experimental data for HfTe_3 include the original structural characterization¹⁸, and the determination of its basic magnetic properties (temperature-independent diamagnetism)¹⁹. In addition, it has been recently reported by scanning tunneling

spectroscopy that Hf/HfTe₂/HfTe₃ films exhibited a superconducting gap-like spectra²². HfTe₃ and ZrTe₃ are iso-structural materials whose features raise the possibility that HfTe₃ may also exhibit the coexistence of SC and CDW state. Therefore, it would be an important task to synthesize the high quality bulk compound, and to explore the aforementioned electrical phenomena.

By modifying the original synthesis conditions^{18,19}, polycrystalline HfTe₃ samples have been successfully synthesized. The crystal structure has been analyzed using Rietveld refinement and the first experimental evidence of metallicity in this material is reported. The resistivity data exhibits an anomaly suggestive of a CDW formation at ~82 K and subsequently zero resistivity below 2 K. By the application of hydrostatic pressure, the resistivity anomaly shifts to higher temperature. In addition, we note that HfTe₃ is highly air-sensitive, where the behaviour of ρ -*T* characteristics changes from metallic to insulating upon exposure in air (See Supplementary information).

Results and Discussion

Key requirements to synthesise single phase HfTe₃. Suitable reaction conditions to produce single phase HfTe₃ crucially depend on the maximum reaction temperature¹⁹. During this investigation it has been found that a slow cooling rate is also a key requirement. In brief, the favoured phase was HfTe₂ at a higher temperature range (≥ 530 °C) and HfTe₅ at lower temperature regions (≤ 470 °C). As reported by Brattås *et al.*, we confirmed that the sintering condition of c.a. 500 °C indeed favours the growth of the HfTe₃ phase¹⁸. However, when rapid cooling from 500 °C (*e.g.* quenching in water) was applied¹⁹ the majority phase became HfTe₂ together with unreacted tellurium. On the other hand, when slow cooling was performed (approx. -0.25 °C/h) until 470 °C after which the ampoules were cooled to room temperature at a rate of approx. -5 °C/h, then single phase HfTe₃ could reproducibly be synthesised. The results suggest that HfTe₃ primarily forms by reaction with the tellurium vapour upon cooling. If the reaction vessel is quenched, the solidification of the tellurium prevents its uptake and HfTe₂ becomes the preferred phase. Namely, it is found that HfTe₃ is the least thermodynamically stable phase within the Te-rich Hf alloys and as a result in order to inhibit the formation of trace amounts of HfTe₂/HfTe₅, it is necessary to control precisely both the sintering temperature and the cooling rate.

Crystallographic analysis. Figure 1(a) shows the powder X-ray diffraction (PXRD) result for HfTe₃ together with the result of the Rietveld refinement using ZrSe₃ as a reference model²³, where the result was consistent with the monoclinic crystal symmetry (space group P2₁/m). Figure 1(b) represents the crystal structure

of HfTe₃ which is the pseudo-one-dimensional (1D) structure. As seen in Fig. 1(b), MQ₆ trigonal prismatic units propagate along the *b*-axis resulting in chain-like anisotropic crystal growth. By projection down the *b*-axis it can be clearly seen how the chains are bonded together by Van der Waals forces (see Fig. 1(c)). Reasonable values of R_{wp} = 8.47%, R_p = 6.60% and $\chi^2 = 1.544$ were obtained. Refined lattice parameters of HfTe₃, *a* = 5.8797(9) Å, *b* = 3.8999(9) Å, *c* = 10.0627(3) Å agreed with the previously reported values¹⁹. On the other hand, the angle $\beta = 98.38(8)^\circ$ showed a slight expansion from the originally reported angle of $\beta = 97.98^{18}$. The refinement results are summarized in Table 1. It was confirmed from X-ray fluorescence (XRF) results that the composition ratio of our HfTe₃ was Hf:Te = 26:74 (at%).

Coexistence of SC and CDW. Resistivity of non-air-exposed HfTe₃ reproducibly exhibited metallic behaviour in the temperature range between 0.3 and 300 K as shown in Fig. 2(a). The residual resistivity ratio (RRR) defined as $\rho(275\text{ K})/\rho(4\text{ K})$ is ~2.4, which is lower than that of single crystal ZrTe₃¹¹ but is larger than that of polycrystalline-ZrTe₃²⁴, in which the lower RRR value is thought to arise from strong grain boundary effects. Therefore the influence of grain boundaries is likely to play a role in the reduction of RRR. The inset of Fig. 2(a) shows the temperature derivative of the resistivity $d\rho/dT$ and reveals a resistivity anomaly at 82 K assumed to be indicative of a CDW formation, where the CDW formation temperature T_{CDW} is defined as the temperature at which $d\rho/dT$ exhibits a minimum. At T_{CDW} the CDW gap is developed and the resistance anomaly appears owing to a reduction in the density of states at E_F due to the CDW formation. Below 2 K, the resistivity showed a sharp drop exhibiting a SC transition at 1.8 K (T_c^{onset}) and reached zero (T_c^{zero}) at 1.45 K as can be clearly seen in Fig. 2(b). By increasing the applied current, a broadening of the SC transition was observed and it was accompanied by a downward shift in T_c^{onset} and T_c^{zero} , whereas the normal state resistivity remains unchanged. The result suggests a weakening in the SC state as well as a decoupling of the Josephson junctions between individual SC grains of the polycrystalline material. *I*-*V* characteristics measured at $T > T_c$ and $T < T_c$ revealed ohmic and non-ohmic behaviour, respectively. N.B. In the present study, we observe that HfTe₃ shows a rapid weakening of its metallic state within minutes of exposure in air (see Supplementary Fig. S1). This is likely the result of an insulating layer (such as tellurium oxides) forming around the individual grains of the polycrystalline material. The results emphasize that if one is to observe the intrinsic properties of HfTe₃, any measurements must be conducted in the absence of air.

Figure 2. (a) Temperature dependence of the resistivity for HfTe₃. Data show a hump-like feature at ~80 K together with an SC-like transition at 1.8 K. Inset shows that the resistivity anomaly occurs at approximately 82 K (sample #A). (b) Current dependency of the resistivity of HfTe₃ below 3 K. T_c^{onset} is approximately 1.8 K and T_c^{zero} is reached c.a. 1.4 K for a current of 0.05 mA. By an increase in current, both the T_c^{onset} and T_c^{zero} show a shift to lower temperatures (sample #B).

Figure 3. (a) Pressure dependence of resistivity at the range of $P=0-1$ GPa. (b) $d\rho/dT$ in the range of 30–150 K as a function of pressure. The minimum of the dip structure shows a shift to higher T with increasing P . Color coding between (a) and (b) are matched to indicate the same pressure values (sample #D).

Behaviour under high-pressure. By the application of hydrostatic pressure (P), the resistivity anomaly gradually shifted to higher temperatures up to ~99 K for P approaching 1 GPa as shown in Fig. 3. Similar behaviour has been reported for ZrTe₃ where in the case of an application of $P \leq 2$ GPa the T_{CDW} was increased and the SC suppressed. At $P \geq 5$ GPa the CDW was fully quenched and gave way to reemergent SC, where T_c increased to ~4.5 K when $P \sim 11$ GPa¹⁵. In addition, in the case of HfTe₃, SC appeared by applying $P \sim 5$ GPa and a maximum T_c of 4.8 K was attained by applying at $P \sim 20$ GPa²⁵. This suggests the possibility that HfTe₃ is likely to follow the same pattern as other members of the group IV-MTe_x alloys. Namely by further application in pressure, it is expected that the T_{CDW} will eventually be suppressed and T_c will be enhanced.

Electronic structure. Studies regarding the electronic structure of HfTe₃ are limited, but the issue is briefly reported by Felser *et al.* who determined an electronic structure similar to that of ZrTe₃, *i.e.* a metallic state resulting from a large contribution of the Te *p*-bands at the Fermi level¹⁶. These characteristics are supported by later density of states (DOS) calculations^{20,21}. ZrTe₃ exhibits a multi-component Fermi surface with contributions from the Te forming quasi 1D electronic sheets at the boundary of the Brillouin zone and from the Zr a 3D-hole character sheet around the Γ point. The resultant nesting characteristics at the Fermi surface have been determined to be responsible for the CDW formation in ZrTe₃^{16,26–28}. If one considers the iso-structural/electronic relationship between HfTe₃ and ZrTe₃, it is likely that similar interchain interactions between neighbouring Te(2) and Te(3) atoms (see Fig. 1(c)) play a dominant role in the metallicity of HfTe₃¹⁶ which in turn would give rise to the similar Fermi surface with nesting features reported for ZrTe₃. However, it cannot be categorically asserted that the observed resistivity anomaly is due to a CDW formation from our results only. As in the case of ZrTe₃, it would be necessary to confirm any coincidental low-temperature lattice distortions²⁹ as well as to observe the features of the Fermi surface around the temperature of the anomaly²⁶. However the similarities between HfTe₃ and ZrTe₃ in the electronic structure as well as the results of the temperature/pressure dependence of ρ are strong indication that the observed resistivity anomaly for HfTe₃ is indeed the result of a CDW formation.

Conclusion

In summary, we have established a reproducible synthesis method for high-quality polycrystalline HfTe₃ and showed that it is an acutely air-sensitive material. By using high-quality HfTe₃ we found that the quasi-1D HfTe₃ is a novel SC with $T_c \sim 1.4$ K, and the SC state coexists with the CDW state which appears at $T_{CDW} \sim 82$ K. Furthermore, we provided the first accurate crystallographic data by Rietveld refinement of the PXRD of HfTe₃.

Methods

Single-phase polycrystalline HfTe₃ samples have been prepared using standard chemical vapour transport techniques. Ground mixtures of a 1:3 molar ratio of powdered Hf and Te were sealed in silica ampoules under a vacuum of c.a. 3 mTorr using a rotary pump. The ampoules were heated in a box furnace using the reaction procedure described in the results and discussion. To prevent exposure to air, all sample preparation was conducted in an argon filled glovebox.

PXRD was carried out using a Rigaku Smartlab diffractometer in flat plate geometry with a Cu K α radiation ($\lambda = 1.54056$ Å). Diffraction data were typically collected for $5^\circ \leq 2\theta \leq 80^\circ$ with a 0.01° step size with scan times of 3 hours. Rietveld refinement was performed using the GSAS software package via the EXPGUI interface^{30,31}. XRF analysis was performed using a JEOL JSX 1000 S ElementEye.

Resistivity measurements were performed on cold-pressed pellets using a standard four-terminal setup. Measurements for sample #A were performed between 0.3 and 300 K using an Oxford Instruments 3He cryostat, data were collected by an AC method using a low-noise amplifier and two lock-in amplifiers. Measurements for sample #B were performed by a DC method between 0.3 K and 15 K using a Quantum Design PPMS equipped with an adiabatic demagnetization refrigerator. The resistivity for Samples #C and #D were also measured by a DC method between 2 and 300 K using a closed cycle helium refrigerator. High-pressure resistivity measurements (up to 1 GPa) were performed using a BeCu/NiCrAl clamped piston-cylinder cell using Daphne 7373 as the fluid pressure transmitting medium with Pb employed as a manometer.
