OPEN Phase-transfer induced room temperature ferromagnetic behavior in 1T@2H-MoSe₂ nanosheets

Baorui Xia¹, Tongtong Wang¹, Wen Xiao², Rongfang Zhang², Peitao Liu¹, Jun Ding², Dagiang Gao^{1,2} & Desheng Xue¹

Manipulating electronic and magnetic properties of two-dimensional transitional-metal dichalcogenides has raised a lot of attention recently. Herein we report the synthesis and ferromagnetic properties of phase-transfer induced room temperature ferromagnetic behavior in 1T@2H-MoSe₂ nanosheets. Experimental results indicate the saturated magnetization of the 1T@2H-MoSe2 compound increases first and then decreases as the increasing of 1T-MoSe₂ phase, where 65.58% 1T-MoSe₂ phase incorporation in 2H-MoSe₂ could enhance the saturated magnetization from 0.32 memu/g to 8.36 memu/g. Besides, obvious magnetoresistance behaviors are observed in these samples, revealing their potential applications in future spintronics.

Diluted magnetic semiconductors (DMS) have been of great interest due to their possibility for high temperatures beyond room temperature predicted by Dietl et al. in 2001¹, where clear room temperature ferromagnetism (RTF) has been widely studied in oxide based diluted magnetic semiconductors such as ZnO and SnO₂²⁻⁵. On the other hand, owing to the increasing need of micro devices in modern electronic, nano-scaled semiconductors are more and more popular in applying to these fields⁶⁻⁸. In this case, two-dimensional (2D) transitional metal dichalcogenides (TMDs) became the ideal materials to meet the demand for applications in nano-scaled semiconductor devices⁹⁻¹¹. In recent years, TMDs have been investigated by many researchers owing to their excellent properties in various fields such as nanoscale field-effect transistors, phototransistors, sensors, lithium-ion battery, and photocatalysts¹²⁻¹⁵. Among these TMDs, MoX₂ (X = S, Se) are the most studied materials, which are popular for their unique graphene-like structures (X-Mo-X), bounded together by van der Waals interactions^{16,17}. Compared with graphene, MoX_2 possesses intrinsic large band gaps (1.3–1.8 eV) in their monolayer form and flexibility of MoX₂ atomic layers, which makes it possible for their applications in nanoelectronic and optoelectronic devices on both conventional and flexible substrates^{18–21}. Beyond that, the well defined spin-splitting property of MoX_2 makes them as promising spintronics devices^{22,23}. However, with the development of spintronics, semiconductors possessing excellent magnetic properties are in great demand for applications²⁴. Therefore, realizing and manipulating ferromagnetism in MoX_2 nanosheets become the critical issue and challenging problems to be solved. Just like traditional DMSs materials, doping magnetic ions into MoS_2 is an efficient way to induce the RTF, which are reported both theoretically and experimentally in recent years²⁵. Results indicate that all the dopants induced ferromagnetism are mainly focusing on the defects, however, magnetic clusters, and secondary phases are possible as the main contributors to the observed ferromagnetism²⁶⁻²⁸. For this reason, some non-magnetic ions are selected as the dopants in experiments. As reported in our previous work, copper ions as the dopants are induced in MoS_2 nanosheets to make it become ferromagnetic and obtained a high Curie temperature up to 930 K²⁹. What's more, many other ways to introduce ferromagnetism into two dimension TMDs materials have been explored both theoretically and experimentally. It is predicted that ferromagnetism appears when MoS₂ nanoribbons are formed with zig-zag edges³⁰⁻³⁴. Besides, the intrinsic structure transformation could be an efficient method to introduce robust RTF^{35,36}, where the structure transformation related RTF in MoSe₂ is seldom reported. In this paper, we

synthesize $1 \text{ T}@2\text{H}-\text{MoSe}_2$ nanosheets with different phase rations by two-step solvothermal method. Results indicate that the $1 \text{ T}@2\text{H}-\text{MoSe}_2$ nanosheets with different phase rations show the variation magnetic properties. where $65.58\% 1 \text{ T}-\text{MoSe}_2$ phase incorporation in $2\text{H}-\text{MoSe}_2$ could enhance the saturated magnetization from 0.32 memu/g to 8.36 memu/g. Besides, the obvious magnetoresistance behaviors reveal their intrinsic RTF and their potential applications in future spintronics.

Results and Discussion

We synthesize $1 \text{ T}@2\text{H-MoSe}_2$ nanosheets by two-step solvothermal method (the schematic diagram is shown in Fig. 1(a))³⁵ where phase-transferred MoSe₂ nanosheets with 0 h, 4 h, 8 h, and 20 h are labeled as S0, S4, S8 and S20 respectively in the following passage. X-ray diffraction (XRD) patterns of the samples are shown in Fig. 1(b). According to the standard PDF card of MoSe₂ (JCPDS No. 29–0914), the diffraction peaks are located at 31.4°, 37.9°, and 55.9°, which are related to certain MoSe₂ crystal planes of (100), (103), and (110), respectively. The 2H or 1 T structure can not only be identified by these three peaks owing to the further atomic structure should be investigated, the results of which will be discussed in what follows in the passage. Figure 1(c) shows the SEM image of synthesized MoSe₂ nanosheets (S8), and it can be seen that the obtained MoSe₂ nanosheets are condensed and assembled thin layers. SEM images of other samples are provided in Supplementary Information. Besides, EDS analysis results of S8 are presented in Fig. 1(d–f). Within the uniform distribution of light and shade contrast of elemental images captured by a detector, the existence of molybdenum and selenium can be easily observed, demonstrating the element consistence of MoSe₂ nanosheets.

Figure 2(a) is the 1 T@2H TEM image of S8, two different regions are obviously compatible. We can see typical molybdenum atoms in either 2H or 1 T structure possess six selenium atoms, which are triangular prism and octahedral configuration, respectively (white circles). Additionally, the panels can be seen in high resolution transmission electron microscope (HRTEM) image and the interplanar spacing is calculated to be 0.27 nm, indicating the (110) panels of 2H MoSe₂ (JCPDS No. 29-0914). Figure 2(b) shows the high resolution X-ray photoelectron spectra (XPS) of the four samples. In terms of Mo 3*d* regions, all the spectra can be well fitted by two sets of peaks. The peaks around 229.3 eV and 232.5 eV correspond to 3*d* 5/2 and 3*d* 3/2 components of 2H structure MoSe₂. Yet once the 1 T structure is induced, these two peaks will shift to lower binding energies of 228.4 eV and 231.6 eV. As shown in Fig. 2(c), the 1 T concentrations of S4, S8 and S20 are calculated from Mo 3*d* spectra as 30.19%, 65.58% and 83.95%, respectively. Figure 2(d) shows the Raman spectra of these four samples, from which the peaks at 150.7 cm⁻¹ and 289.4 cm⁻¹ in S4, S8 and S20 can be observed. These two peaks, marked as J₂ and E_{2g}¹, are the exclusive peaks of MoSe₂ 1 T structure, consisting with the work reported by Uttam *et al.*³⁷. Herein, the

intensity of these two peaks growing with the amount of 1 T phase, with respect to A_{1g} peak, which also demonstrates the phase transformation from 2H to 1 T.

Besides, we investigate the magnetic properties of 1 T@2H-MoSe₂ nanosheets. The room temperature magnetic hysteresis loops of samples are shown in Fig. 3(a), where the linear background signals have been subtracted³⁸. Compared with S0, the saturate magnetization (M_s) for S4 and S8 increases from 0.32 memu/g to 1.6 memu/g, and then to 8.36 memu/g, respectively, suggesting that introduction of 1 T phase could lead to the ferromagnetic ordering in MoSe₂ nanosheetes. From the inset of Fig. 3(a), it can be seen that the M_s increases until the 1 T concentration raises to 65.58%, dramatically, the M, decreases to 2.6 memu/g in S20 (83.95% 1 T phase). Figure 3(b) gives the isothermal hysteresis loops of S4 from 10 K to 300 K, the inset of which shows the zero-field-cooled (ZFC) and field-cooled (FC) curves. Typical ferromagnetism property has been characterized by these curves, thus the Ms decreases with the increasing of the measured temperature. The ZFC-FC curves suggest that the Curie temperature of the sample is above the room temperature. Besides, no blocking temperature can be found during the cooling process, indicating that there is no ferromagnetic cluster occurs in S4³⁹. Besides, the electron spin resonance spectra (ESR) of four 1 T@2H-MoSe2 samples are shown in Fig. 3(d). As we can see, the resonance occurs in 325 mT (g = 1.98), corresponding to the paramagnetic resonance of the four samples. Besides, the distinct resonance signal raises up in S4, S8 and S20, nearly at 250 mT (g = 2.57), corresponding to the ferromagnetic resonance of these MoSe, nanosheets, in accord with the M-H results in Fig. 3(a). In addition, obvious magetoresistance (MR) behaviors are observed in sample S4, S8 and S20. As described in Fig. 3(d), MR values are negative with the magnetic field range of [-0.1 T, 0.1 T] and evolves from 0% to -0.22% with the magnetic field increased to 0.1 T. While for the S4 and S20, the lowest MR value are only -0.07% and -0.09%, respectively. The MR values vary with the saturate magnetization of three samples, also confirm the observed ferromagnetism is intrinsic in 1 T phase incorporated MoSe₂ nanosheets⁴⁰.

Above results indicate that the M_s decreases when the concentration of 1 T phase increases up to 83.95%. Therefore, we assume that the observed ferromagnetism is related to the relative ratio of both 1 T and 2H phase in MoSe₂ nanosheets. To verify this, it is necessary to conduct further experiment. Zhao *et al.* report that transformation from 1 T to 2H can be conducted by annealing the 1 T samples under Ar ambitions⁴¹, so we perform the re-transformation with annealing the S20 in high purity Ar for 1 h and 2 h under 250 °C, respectively. The obtained samples are subsequently studied by using M-H hysteresis loops and Raman spectra. It can be seen from Fig. 4(a), the M_s increases by four times after annealing for 1 h, but decreases as the annealing time prolonged to 2 h. In Fig. 4(b), the peak of A_{1g} mode appears together with the peaks of J₂ and E_{2g}¹ modes decaying after annealed for one and two hours. Both the two results indicate that the coexistence of 1 T and 2H phase is the ultimate condition for observed ferromagnetism in MoSe₂ nanosheets.

To explore the origin of the observed ferromagnetism, it is necessary to point out how the magnet moment induced with the 1 T phase incorporated in 2H matrix. As we all know, 4d orbital has five degenerate states, called as d_{xz} , d_{yz} , d_{xy} , d_{x}^2 , d_{x}^2 and d_{z}^2 . In 2H phase, hexagonal symmetry configuration could induce splitting of 4d orbitals into three orbitals of closely spaced energies. In this case, these five orbitals unit into three groups: $d_{xz} \notin d_{yz}, d_{x^2-y^2} \notin d_{xy}$ and d_z^2 , as described in Fig. 4(c), two 4d electrons of Mo⁴⁺ occupied d_z^2 orbital spin-antiparallely, as a result of which the Mo atoms in 2H phase structures exhibit nonmagnetic. While for 1 T phase of the MoSe₂, the Mo atoms are surrounded by six Se atoms with octahedral coordination, therefore, the five orbits unit into two groups: $d_{xz} \notin d_{yz} \notin d_{xy}$ and $\dot{d}_z^2 \notin d_{x^2-y^2}$. The $d_{xz} \notin d_{yz} \notin d_{xy}$ orbits have lower energy level, therefore, determined by Hund's rule, the two 4d electrons occupied solely in two of them spin-parallelly, causing the net magnet moments of 1 T phase Mo atoms^{35,37}. For the robust ferromagnetism observed in 1 T@2H MoSe₂ nanosheets, bounded magnetic polaron (BMP) model is suitable to explain the magnetic origin. Figure 4(d) gives the schematic diagram of BMPs in 1 T incorporated MoSe₂ nanosheets. During the solvothermal synthesis process, many selenium vacancies formed in MoSe₂ nanosheets, as a result, BMPs could be developed with localized holes and a large number of Mo⁴⁺ spins are bounded around the Se vacancies. The Mo⁴⁺ spins near a Se vacancies could align their spins parallel to the vacancy spin, leading to the formation of a BMP. It has been reported by Cai et al. that the 2H-1 T transformation always occurs near the defects³⁵. Based on this phenomenon, we proposed that in low 1 T concentration case, the Mo⁴⁺ spins emerged near the selenium vacancies and form BMPs. These BMPs began to overlap and ferromagnetic coupled, giving the origin of ferromagnetism and risen of magnetization. However, when the amount of 1 T concentration added up to 83.95%, the 1 T regions expand and produce more Mo⁴⁺ spins in the regions where the Se vacancy density is much lower, as shown in Fig. 4(d). In this case, majority of these Mo atoms are around Se atoms compared with Se vacancies, and they are either anti-ferromagnetic coupled by Se atoms or existed as isolated Mo⁴⁺ spins, resulting the decreasing of magnetization macroscopically. This could cause the weaken of ferromagnetism in $MoSe_2$ nanosheets and this is why we observe the decreased M_s in S20.

Conclusions

In summary, we synthesize the 1 T phase incorporated 2H-MoSe₂ nanosheets by solvothermal method, the crystallinity of all samples have been confirmed by structural characterization methods. After the phase transformation, RTF of MoSe₂ can be improved, with the M_s from 0.32 memu/g up to 8.36 memu/g. At the same time, the obtained MoSe₂ nanosheets exhibit obvious magnetoresistance behavior with MR value up to -0.22% when the external magnetic field applied to ± 0.1 T. The induced Se vacancies may affect the formation of the BMPs and their interactions, in turn controlling the magnetic moments of the 1 T phase incorporated MoSe₂ nanosheets. The obtained results enlighten on the development of ferromagnetic MoSe₂ nanosheets and provide them a paradigm of application of spintronics devices.
